# Again Crane *leads the field*

THE American Society of Sanitary Engineers issue a warning of danger in the use of plumbing fixtures which permit the possibility of water pollution through back-siphonage of waste into the water supply system. At a meeting recently held in Washington, D. C., committees were appointed to devise ways and means of protecting the populace against this danger.

Several years ago it was observed by noted health authorities in some of the country's most famous hospitals, in spite of all precautions, post-operative infections were occurring and water-borne diseases were spreading. Crane Co. collaborated with medical authorities, and their engineers set out to learn the cause and devise a remedy.

The first definite results were found when it was proved that a partial vacuum created in the water supply system, due to a drop in pressure, drew polluted water from waste lines into the water supply. Further research showed the condition was common; at many points fresh water lines were subject to pollution by siphonic action through the valves of such fixtures as closets, slop sinks, baths, lavatories, fountains, and aspirators.

To overcome this, Crane engineers worked out a line of vacuum breaker valves which eliminate all danger of back-siphonage.

*Crane vacuum-breaker valve which eliminates the pollution of fresh water lines by back-siphonage*

So successfully have Crane engineers applied this principle to all fixture valves where back-siphonage threatens, and extended it by raising the spouts of lavatories, baths and drinking fountains, that progressive Health Departments now insist hospitals and institutions use only such fixtures and valves as adequately guard against back-siphonage. You can see these materials at your Crane Exhibit Rooms, or get full information concerning them by writing Crane Co.

# A Basis of Rationing for Federal Prisoners<sup>\*</sup>

PAUL E. HOWE, PH. D., AND A. H. MACCORMICK

*Senior Biological Chemist, U. S. Department of Agriculture; and Assistant Director, Bureau of Prisons, U. S. Department of Justice, Washington, D. C.*

A BASIS for determining the cost of food and a measure of the adequacy or inadequacy of the diets were found to be necessary for the economical, satisfactory and adequate feeding of the inmates of federal prisons or reformatories. Such a basis must be applicable to the average inmate, irrespective of the type of his work, on the assumption that the variation in activity is covered by the variation in appetite.

To determine a basis of rationing, two main courses of procedure were open: (1) to accept data already in existence as to what constitutes an adequate diet with regard to kind and to quantities of foods to be fed; and (2) to determine the amounts and kinds of food used in the various prisons, under conditions that were reasonably effective from the point of view of preparation and distribution, and satisfaction under the restricted conditions that exist in a prison, and finally to modify the result so obtained with regard to dietary requirements as dictated by present-day knowledge of nutrition. We adopted the latter as one that would give assurance of success when modifications were introduced. Furthermore, such a procedure enabled us to evaluate the operations of prisons under existing conditions and furnished a basis for judging the effects of future changes.

Data were assembled over a period of a year from 5 federal institutions having a total average daily population of about 10,000 men: the penitentiaries at Atlanta, Leavenworth, Fort Leavenworth, and McNeil Island, and the reformatory for men at Chillicothe. These data represented the ordinary operation of prisons, with a tendency to modification in the direction of an increased consumption of vegetables and in some cases considerable variations in the consumption of milk, due to advice to the stewards or variations in farm practices.

The foods were subdivided into type groups. The consumption

# INDUSTRIAL HYGIENE

**Cyanide Poisoning**—The most important industrial forms of cyanide are hydrocyanic acid and the sodium and potassium salts of this substance, NaCN and KCN. Hydrocyanic acid is a volatile liquid, both aqueous and alcoholic solutions decompose spontaneously. The salts are crystalline in nature; in solution they decompose, when heated above 176° F., or when they are acted upon by acids, and in decomposing they give off cyanide vapors. These compounds are used in industry for the extraction of gold and silver, for electroplating, and in certain metal cleaning polishes.

Poisoning occurs by skin absorption, by inhalation of the gas and inhalation and ingestion of the crystalline compounds. The cyanides exert a peculiar asphyxiating action on the cells of the body. So completely and rapidly are the latter deprived of their ability to utilize oxygen that injury or death may ensue very rapidly. Cyanide rash often follows the use of these compounds in industry.

Contrary to the belief held by many physicians, cyanide may produce chronic as well as acute poisoning. In the present contribution brief abstracts are presented of 3 cases of chronic cyanide poisoning taken from the files of the Division of Industrial Hygiene of the New York State Department of Labor.

The immediate effects in the first case were nausea, dizziness and unconsciousness, followed during the next 6 weeks by weakness and palpitation, with incapacitation for work.

The second case is that of a gold plater, with an occupational history of 20 years' duration. He made up a large supply of KCN solution one day; that evening he developed severe abdominal

pains and convulsions and later developed persistent vomiting. This man was forced to give up his work; he lost 20 pounds in weight, and was incapacitated by weakness, headache, dizziness, muscular cramps, and recurring attacks of abdominal pain and vomiting.

In the third case the physician who examined the victim 3 years after the onset of symptoms found him entirely disabled with paralysis and wasting of the muscles of the arms and legs.—Adelaide Ross Smith, M.D., *Indust. Bull.*, 11, 6: 169 (Mar.), 1932. L. G.

**Procedure for Establishing Optimum Air Conditions for Light and Heavy Work**—The present contribution deals with the study of atmospheric conditions lying in that range between the optimum comfort zone on the lower side and the onset of disturbance in the heat regulating apparatus on the upper border. This zone is not characterized by any pathological manifestations, but nevertheless discomfort and fatigue causing a reduction in working output may be present.

The authors point out that according to the data of Hill the optimum temperatures for certain workers are exceedingly low, for example,  $-21^{\circ}$  C. for a stone mason and  $-31\frac{1}{2}^{\circ}$  C. for a man sawing wood. Obviously such temperatures cannot be proposed as practical optimums. In addition they point out that under certain conditions of air currents, the kata thermometer of Hill does not yield reliable estimates of the cooling power. The effective temperature index determined from sensation is applicable to Americans at rest or engaged in light physical work. No data are presented for heavy physical labor.

When writing to Advertisers, say you saw it in the JOURNAL

cases, but in a much milder degree than that present in the earlier group of cases.

In the early cases mesothorium predominated while in the later cases radium has been detected in the postmortem examinations. It would appear, then, contrary to the belief of certain persons, that radium as well as mesothorium is responsible for the production of pathology. The bone lesions in these later cases was found to be osteogenic sarcoma, and Dr. Martland states:

It would now appear that we have reached a point when we will no longer encounter the anemias and jaw necroses seen in the earlier cases, but instead the girls will appear with terrible, usually rapidly growing, embryonal or anaplastic osteogenic sarcomas, the result of radioactivity.

Previous autopsies disclose the fact that the lethal amount of radioactive substances in the skeletons of deceased persons varied between 10 to 180 micrograms. The rays emitted by such deposits consist of 92 per cent alpha rays and 8 per cent beta and gamma rays. These alpha rays are said to be the most potent and destructive agent known to science. Mesothorium emits 5 particles as compared to 4 emitted by radium. It is interesting to note that the 10 micrograms, that is, 1/100,000 gram, is sufficient to produce death, and yet this quantity is so small as to be invisible and undetectable by any known chemical method of analysis.

An interesting discussion of the incidence of carcinoma of the lung in cobalt and pitchblende miners is presented. A few years ago a study of 154 miners was made using modern diagnostic methods. During a period of 3½ years, 21 of the miners died and in 13 cases (62 per cent) a diagnosis of carcinoma of the lung was made at autopsy. The belief is now held that radioactive emanations are the causative factors in the production of these cases of lung cancer. It is true that the concentration of radium emanations in these mines is quite low,

nevertheless the exposure is of long duration, 20 to 30 years prior to the development of the tumors.

The author of this valuable contribution issues a warning against the use of radioactive drinking water.—*Month. Labor Rev.*, U. S. Department of Labor. 34, 4 (Apr.), 1932. Abstr. from The Occurrence of Malignancy in Radioactive Persons—Harrison S. Martland, *Am. J. Cancer*, Oct., 1931. L. G.

**Cadmium Poisoning:** 1. The History of Cadmium Poisoning and Uses of Cadmium—This contribution presents a very valuable summary of the physiologic and pharmacologic action of cadmium. Reviewing the literature in a very complete manner the author concludes that cadmium is relatively toxic for laboratory animals and that it possesses a direct paralyzing action on the central nervous and vasomotor systems. This material has a tendency to be stored chiefly in the liver and kidneys, and elimination, which is very slow, is effected through the kidneys and gastrointestinal tract.

In the second portion of this paper, cadmium poisoning in man is reviewed, and a discussion of the chemistry and industrial uses of cadmium is presented. Finally a list of the health hazards associated with the use of cadmium closes this interesting report.—Leon Prodan, *J. Indus. Hyg.*, 14, 4 (Apr.), 1932.

L. G.

**Japanese Association of Industrial Hygiene**—The Fourth Annual Meeting of the Japanese Association of Industrial Hygiene was held in the city of Nagoya November 14–19, 1931.

The subjects covered were the influence of gymnastic exercises on the health of industrial workers, the organization of factory clinics, health insurance and medical practitioners, high temperatures and humidity in spinning mills, the protection of women in pregnancy and after

of carrots, to a cow at the end of the winter stall feeding period resulted in an increase not only in the carotene content but also in the vitamin A content of the butter-fat.

3. The degree of pigmentation of butter-fat, when adequate carotene is available in the diet, is determined by bread. Butter-fat derived from Jersey cows gave a yellow value twice that obtained with butter-fat derived from Shorthorn cows under similar nutritive conditions.

4. When the cow is at pasture the output of carotene and vitamin A in the butter-fat is very small in comparison with the amount of carotene available in the diet. On the other hand, during stall feeding upon a diet almost devoid of carotene the reserves of vitamin A available in the liver and elsewhere may be insufficient to meet the demands of prolonged lactation.

These deductions with respect to vitamin A and carotene are based on colorimetric determination.—Thomas Moore, *Biochem. J.*, 26:1, 1932.

**The Value of Some Vegetables in Nutritional Anemia**—In this experiment, dried spinach, lettuce, tomato, asparagus, broccoli, and turnip greens were studied for their effectiveness in curing nutritional anemia in the rat. Dried spinach when fed *ad libitum* and yielding an average daily intake of 0.43 mg. of iron and 0.0061 mg. of copper, effected hemoglobin regeneration in 3 to 4 weeks.

Lettuce plus tomato mixture, asparagus, lettuce, spinach, and broccoli—all fed at a level affording 0.20 mg. of iron but different amounts of copper—permitted hemoglobin regeneration in 4 to 5, 5 to 6, 6 to 7, 6 to 7, and 7 to 8 weeks, respectively, in the order of decreasing copper intake. Since variations in the iron and copper content of these vegetables are known to exist, it is to be borne in mind that a different order of anti-anemic potency would probably result from another set of the same vegetables. Turnip greens fed at a level furnishing 0.425 mg. of iron and 0.0179 mg. of copper brought about rapid regeneration in 3 to 4 weeks. When

fed at the same level of iron, a lettuce and tomato combination was found more effective than lettuce alone.

The above vegetables are, therefore, important sources of the minerals concerned in normal blood formation.

Iron alone or copper alone, when fed in the form of inorganic salt solutions, permitted only partial blood regeneration, whereas solutions containing both iron and copper effected rapid recovery of hemoglobin.—Harold Levine, F. B. Culp and C. B. Anderson, *J. Nutrition*, 5:295 (May), 1932.

**Relative Quantities of the Heat-Stable and Heat-Labile Fractions of Vitamin B in Raw and Evaporated Milk**—In this experiment, three different methods were used:

A. The separation of the two factors by fractionation of the milk solids and confirmation that the limiting factor is the heat-labile fraction.

B. Quantitative estimation of the relative amounts of the heat-labile fraction in raw and evaporated milks.

C. Quantitative estimation of the heat-stable fraction in raw and evaporated milks.

The results in the growth experiments show that milk contains all the water-soluble vitamins necessary for the growth of the rat, but that relatively large volumes must be taken to obtain optimum growth. Commercial evaporation has not seriously affected these substances.

These experiments have shown that commercial evaporation of cows' milk destroys about one-sixth to one-fifth of the antineuritic heat-labile fraction. All cows' milk seems to be quite low in this factor, however, 25 c.c. (3.49 gm. solids) being required per rat per day for optimum growth. Milks do not apparently vary widely in their antineuritic content as purchased on the market.

There is no identifiable destruction of the heat-stable, growth-promoting fraction during commercial

# ANNOUNCING A NEW TELETYPEWRITER SERVICE

THE BELL SYSTEM offers to the public a new Teletypewriter Service. Any subscriber to this service may be connected, through the teletypewriter "central," to any other subscriber, whether he be around the corner or across the continent. Subscribers can type back and forth by wire, for short or long periods, just as they now hold conversations by telephone.

This important development for the business world parallels the other progress which is constantly being made in the telephone art.

Messages, inquiries, reports—typed in one office—are instantly and accurately reproduced on the other subscriber's teletypewriter. Typewritten copies made by both sending and receiving machines are available for permanent records. The principal feature of this new service, which distinguishes it from existing private line teletypewriter service, is that any subscriber may ask

for any other subscriber and be connected immediately.

Further information about this new development in nation-wide communication will be furnished gladly by your local Bell Telephone Business Office.

Teletypewriter Service provides two-way communication.

Speed of connection is as fast as telephone service.

A typewritten record, one or more copies, is produced simultaneously by both sending and receiving machines.

Material transmitted may be recorded on forms if desired.

Teletypewriters are like ordinary typewriters in appearance.

Teletypewriters can be operated by any one who can operate a typewriter.

You can use Teletypewriter Service any time you need it.

A most economical form of record communication.

AMERICAN TELEPHONE AND TELEGRAPH COMPANY

later medical care, and in the reduction of and prevention of disease among workers in industry.

CHARLES A. KOFOID

**Man and Microbes**—By *Stanhope Bayne-Jones, M.D.* Baltimore: *Williams & Wilkins*, 1932. 128 pp. Price, \$1.00.

This volume is one of the Century Progress Series. The name of the author assures us that it is authoritative. It is well and interestingly written, and will serve a useful purpose for the class of people for whom it is intended. With these limitations in mind, it can be thoroughly recommended from every standpoint. MAZÛCK P. RAVENEL

**The Social and Ethical Significance of Nursing**—By *Annie W. Goodrich.* New York: *Macmillan*, 1932. 401 pp. Price, \$3.00.

Nurses everywhere will hasten to read this book which is a compilation of a series of addresses made by the author, who is one of the most brilliant nurses in America, over a period of more than a decade. These addresses deal with the nurse in her relation to ethics, education, the hospital, the community, the university, and the world.

Nurses will travel long distances to hear Miss Goodrich talk, and all their powers of concentration are called into play in listening, because her language is not that of the ordinary expository writer but that of the most finished literary scholar who draws from a wide range of literature for quotations to prove her points. She leaves her listeners and her readers with minds in the clouds and seeing some of the visions she sees of what the social and ethical significance of nursing has been, is now, and can be in the future. She is a highly inspirational speaker and writer, and might be called the nursing world's "least mortal mind."

This fine book which portrays the

struggles, beliefs and aspirations of the nursing profession in its search for the science of human betterment will be a classic in every nursing library. And it is to be hoped that great numbers of the laity will read it and absorb mentally and emotionally the sound philosophy and ideals of nursing which are so beautifully depicted. EVA F. MACDOUGALL

**Proceedings of the National Conference of Social Work**—*Chicago: University of Chicago Press*, 1931. 702 pp. Price, \$3.00.

In this volume are included the papers of 63 men and women widely known in social work who discuss the problems of social workers and their associates. Personality and health problems, the economic situation, the clinic and dispensary movement, costs of medical care, law enforcement, international aspects of immigration, and educational work with the Indians are among the subjects. In his presidential address, Dr. Richard Cabot particularly emphasizes the need of criterions and of tests of the success or failure of treatment in social case work.

IRA V. HISCOCK

**Child Health and the Community**—By *Courtenay Dinwiddie.* New York: *Commonwealth Fund*, 1931. 80 pp. Price, \$1.00.

Everyone who is concerned with child health is more or less familiar with the child health demonstrations conducted by the Commonwealth Fund. Many have read with the greatest interest the publications of the Fund which give in detail the story of the various demonstrations. Now we have a small volume from the pen of Mr. Dinwiddie which interprets the meaning and results of the four demonstrations—a thoughtful and readable exposition of theory and practice, so to speak. The volume is small but contains valuable material. We have first the background of the demon-

should be even one child guidance clinic in New York City? Why one anywhere? Does it seem strange that there should be so many troubled and troublesome children?"

WHEATON, F. E. Out from Confusion. Survey Graphic 66, 1275 (June 15, 1932).

**Milk-borne Poliomyelitis.**—An unusual opportunity to study an outbreak of poliomyelitis occurred in an institution using raw milk. The author of the paper reports finding his pleo-

morphic streptococcus in the throats and spinal fluids of cases, in well students and in the particular milk at fault. The paper will no doubt cause acute pain in those research workers who have been unable thus far to agree with Rosenow and his findings. However health officials will find in it another reason for pasteurization.

# Mellin's Food

*A Maltose and Dextrins*

**Milk Modifier**

**Mellin's Food**

Made from wheat flour, wheat bran, malted barley and bicarbonate of soda. Contains no sugar, entirely of milk, dextrins, proteins and mineral salts.

## *Constipation in Infancy*

*The Fact that Mellin's Food* makes the curd of milk soft and flaky when used as the modifier is a matter to have in mind when it becomes necessary to relieve constipation in the bottle-fed baby; for tough, tenacious masses of casein resulting from the coagulation of ingested milk, not properly modified, is a frequent cause of constipation in infancy.

*The Fact that Mellin's Food* is free from starch and relatively low in dextrins are other matters for consideration in attempting to overcome constipation caused from the use of modifiers containing starch or carbohydrate compounds having a high dextrins content.

*The Fact that Mellin's Food* modifications have a practically unlimited range of adjustment is also worthy of attention when constipation is caused by fat intolerance, or an excess of all food elements, or a daily intake of food far below normal requirements, for all such errors of diet are easily corrected by following the system of infant feeding that employs Mellin's Food as the milk modifier.

It is characteristic of most babies fed on milk properly modified with Mellin's Food that they are not troubled with constipation.

which became a checking account for the community. It is not the sort of an account on which checks are drawn, nor are its benefits to be reckoned in dollars and cents. Somebody in Pumpkin Creek decided that illness is an emergency which finds most people unprepared; so the women held bazaars, church suppers, and apron sales, and from the proceeds purchased the sick room supplies which are difficult for the average family in the outlying district to obtain. And now, when there is illness, the patient is made as comfortable as possible with clean linens on the bed, and equipment at hand for the necessary treatment. When the invalid recovers, the materials are washed and put away until the next emergency arises. So, although the checking account does not handle capital it does pay 100 per cent in community interest.

Sleepy Hollow has done its share, too. The people are as poverty stricken as the proverbial church mice, and when the rumor came that a dentist had arrived at a neighboring center, and that he was willing to do dental work for those who could not possibly afford to pay for it, there was a community-wide consultation about ways and means. Every parent wanted his child's teeth cared for, but a 20-mile walk was out of the question, and the whole district boasted only one car, if it could be called such. The vehicle was a model T Ford which had long since passed its 15th birthday. One woman, a courageous soul, volunteered to engineer the thing if the wherewithal for gas could be obtained. And it was—pennies—a nickel occasionally—an even more infrequent dime (dollars were unheard of in Sleepy Hollow), and finally the contributions were collected. The "limousine" was packed to the top with assorted children of every age and size, and bounced merrily off upon its way. So were the youngsters introduced to their first dentist, and when they rattled back to their homes at night with missing teeth, and the busy hum of the drill still ringing in their ears, each was the proud possessor of a tooth brush, and the day, to Sleepy Hollow, was a red-letter one, not to be quickly forgotten.

Still another community instituted a different type of service. Health work in this particularly isolated district in the northernmost point of Michigan is as yet a pioneer. The nurse is forced to confine her attentions pretty largely to the school children, since the roads are impassible for a large part of the year, and the families are widely scattered. So it was decided that since she could not possibly reach the preschool children, they would come to her. Accordingly, the school turned itself into a combined nursery and clinic, and gave a "party" for 25 little folk, from 1 year to 5, who came with their

# School ventilating practice is being revolutionized!

THIS  
BOOKLET  
TELLS WHY

School  
Ventilating  
Practice—

Yesterday  
Today and  
Tomorrow

*It is free to physicians*  
**MAIL COUPON BELOW**

For years, physicians specializing on school ventilation problems have recognized certain faults in all ventilating systems. These systems were based on principles which have been proved partly erroneous.

What are these erroneous principles? What are the latest proved principles of ventilation? What problems do they involve? How will school ventilating practice of the future differ from practice of the past? These are some of the questions answered in the booklet, "School Ventilating Practice—Yesterday, Today and Tomorrow."

This booklet has been enthusiastically received by ventilating specialists in all parts of the country. It is an authentic presentation of the school ventilating problem—frankly written.

Physicians interested in school ventilation will find this booklet of great value. It will be sent free upon receipt of the coupon below.

# A study of the composition of bran and its relation to the average diet

IN THE PAST, there has been a tendency to think of bran as being composed largely of indigestible fiber or "bulk." A glance at the table to the right shows that such "bulk" found in bran is less than 10 per cent of the bran content. A considerable amount of the carbohydrates and proteins are digestible. The mineral salts are also in available form.

Recent laboratory experiments tend to further revise popular opinion of bran as merely a "bulk" carrier. Today we know that bran supplies Vitamin B, which is needed to help tone the intestinal tract. In addition, laboratory analysis indicates that bran provides at least twice as much blood-building iron as an equal amount by weight of beef liver. These very real values of bran give it new importance in the diet.

We have seen that the "bulk" in bran averages less than 10 per cent of its composition. In Kellogg's ALL-BRAN special processes of cooking, flavoring and crumbling make the bran finer, softer and more palatable. Within the body, it absorbs a large amount of moisture, forming a soft mass which gently clears the intestines of wastes.

## Composition of Kellogg's ALL-BRAN

<i>Total Carbohydrates</i>	. . 67.2
<i>Protein</i>	. . . . . 13.3
<i>Fiber</i>	. . . . . 7.6
<i>Fat</i>	. . . . . 2.6
<i>Ash</i>	. . . . . 7.6
<i>Moisture</i>	. . . . . 1.7
	<hr/> 100.0

Except in cases of patients who have a highly sensitive intestinal tract, or who suffer from intestinal conditions where the use of any form of fiber would be contraindicated, Kellogg's ALL-BRAN may be safely prescribed.

This delicious ready-to-eat cereal may be served with milk or cream, with fruits or honey, or cooked into fluffy bran muffins, waffles, breads, omelets, etc.—affording the patient pleasing variety in his menus. Appetizing recipes on the red-and-green package. Made by Kellogg in Battle Creek.

# PRICELESS

are the voices of those we love

WHAT PRICE COULD BE SET ON THE VOICE AND  
LAUGHTER OF A LITTLE CHILD A THOUSAND MILES  
AWAY? WHAT PRICE ON THE BRIEF AND REASSUR-  
ING PHRASE, "WE'RE ALL WELL"? WHAT PRICE ON  
A HUNDRED WORDS BETWEEN SEPARATED LOVERS?

What price on a doctor's midnight directions, on the swift response of the fire department, on the relief of anxiety, the cementing of friendship, the unexpected greeting after a long silence?

What price on speed in business, on the smooth running of a household, on leisure or rest without neglect of duty, on shelter in a day of storm?

How can any one say what the telephone is worth to you? We set a value on such visible, physical things as wires, poles, switchboards, instruments, operation. We set a price on telephone service based on what it costs us to render it and to assure its continued growth. These

considerations are fairly exact. But they have little relation to the actual worth of the telephone in your home or office. That is frequently a thing of the spirit and cannot be measured in terms of money.

When you buy telephone service you buy the most nearly limitless service the world affords. Because of it you receive the thoughts and emotions of other people and express your own thoughts and emotions to them. There are no hindering handicaps of time or distance, place or circumstance. For a few pennies a day, you move out of your own little corner in the kingdom of ideas and are free to range where you will.

**Mellin's Food**  
Made from wheat flour, wheat bran, malted barley and bicarbonate of potassium — consisting essentially of maltose, dextrins, proteins and mineral salts.

### *Constipation in Infancy*

*The Fact that Mellin's Food* makes the curd of milk soft and flaky when used as the modifier is a matter to have in mind when it becomes necessary to relieve constipation in the bottle-fed baby; for tough, tenacious masses of casein resulting from the coagulation of ingested milk, not properly modified, is a frequent cause of constipation in infancy.

*The Fact that Mellin's Food* is free from starch and relatively low in dextrins are other matters for consideration in attempting to overcome constipation caused from the use of modifiers containing starch or carbohydrate compounds having a high dextrins content.

*The Fact that Mellin's Food* modifications have a practically unlimited range of adjustment is also worthy of attention when constipation is caused by fat intolerance, or an excess of all food elements, or a daily intake of food far below normal requirements, for all such errors of diet are easily corrected by following the system of infant feeding that employs Mellin's Food as the milk modifier.

( It is characteristic of most babies fed on milk  
properly modified with Mellin's Food  
that they are not troubled with constipation. )

MELLIN'S FOOD COMPANY

Boston, Mass.

Please send "Constipation in Infancy" and "Formulas for Infant Feeding."

# School ventilating practice is being revolutionized!

THIS  
BOOKLET  
TELLS WHY

School  
Ventilating  
Practice—

Yesterday  
Today and  
Tomorrow

## It is free to physicians MAIL COUPON BELOW

For years, physicians specializing on school ventilation problems have recognized certain faults in all ventilating systems. These systems were based on principles which have been proved partly erroneous.

What are these erroneous principles? What are the latest proved principles of ventilation? What problems do they involve? How will school ventilating practice of the future differ from practice of the past? These are some of the questions answered in the booklet, "School Ventilating Practice—Yesterday, Today and Tomorrow."

This booklet has been enthusiastically received by ventilating specialists in all parts of the country. It is an authentic presentation of the school ventilating problem—frankly written.

Physicians interested in school ventilation will find this booklet of great value. It will be sent free upon receipt of the coupon below.

# NERVES TAKE A holiday

She's been the "life of the party" at the expense of her nerves. Aided by the false energy of stimulants she's been a leader in her social life—and physically she's now at the end of her rope.

And so she comes to your office, wondering what's wrong with her . . . little dreaming that it's time for her nerves to take a holiday . . . little dreaming that some of her habits are at fault. If you tell her to give up stimulants . . . to give

up caffein-containing beverages . . . she'll be surprised. It will be difficult for her. For caffein is her old standby. And she'll find it hard to say good-by.

It is in cases like this that Postum is so helpful. For Postum is so good, so out-and-out delicious, so cheering, that it easily takes the place of caffein-containing beverages. Patients *really* relish it.

Postum is not a stimulant. It does not contain a trace of caffein. It is made only from whole wheat and bran roasted to a turn and slightly sweetened.

Instant Postum, made with hot milk, is especially good in cases of undernourishment. It is strengthening, nourishing—and considered by many far more delicious than plain milk. Postum is a product of General Foods Corporation.

We will be glad to send physicians who write us, a special gift package containing a full-size package of Instant Postum, together with samples of Grape-Nuts, Post Toasties, Whole Wheat and Post's Bran Flakes. General Foods, Dept. PV-432, Battle Creek, Michigan. If you live in Canada, write General Foods, Limited, Dept. PV-432, Cobourg, Ontario.

# • PROGRESS •

Tin Cups . . . bubbler fountains  
 . . . the CRANE Newera!

In a drinking fountain it requires careful planning to meet and defeat the threat of contamination which every thoughtless user represents. Such planning distinguishes the Crane Newera bubbler.

Its stream is formed by three jets whose flow is so directed that saliva is carried into the receptor instead of the jet openings.

These openings are protected by an integral shield which prevents foreign matter from falling into them and bars

the user's lips from touching them. Moreover, they are set above the receptor's rim so that all danger of contamination by overflow or back-siphonage is eliminated.

*This Crane Newera three stream drinking fountain bubbler meets the requirements of the Committee on Plumbing of the American Assn. on Public Health.*

Thus the Newera answers the sanitary requirements of institutions, public buildings, parks, and schools. With equal ingenuity it fills the need for economy. It is so designed that all water entering it must pass through a stream regulator; none is discharged into waste pipes.

# The peace that pennies buy

EACH DAY, after breakfast, you bid good-bye to your husband and he is gone. Miles of distance and hours of traveling may separate him from you, yet you do not fear. You have no feeling of his being far away—no sense of loneliness or isolation. For there, within reach of your hand, is your contact with all the world—the guardian of your home . . . your telephone.

All you see is the telephone instrument itself and a few feet of wire. Through the familiarity of use, you are likely to take it for granted in much the same manner as air and water and sunshine. Rarely do you think of the complicated exchanges, the almost endless stretches of wire and the hundreds of thousands of trained employees that are needed to interconnect, through the Bell System, nearly twenty million telephones in this country and twelve million in foreign

lands. No matter where you are, you can command the full use of the telephone. It knows no class or creed. There is no distinction of position. All may share it equally.

Every time you lift the receiver you employ some part of the nation-wide Bell System. Yet the charge for residential use is but a few cents a day. For this small sum you receive a service that is almost limitless in convenience and achievement—so indispensable in emergencies that its value cannot be measured in terms of money.

Thinking of the peace and security it brings each home—of hurried calls to doctors and hospitals—of priceless, necessary talks with relatives and friends—of the many ways it saves you steps and time and trouble throughout the month, you will know why so many millions of people look on the telephone as a member of the family.

# Again Crane leads the field

THE American Society of Sanitary Engineers issue a warning of danger in the use of plumbing fixtures which permit the possibility of water pollution through back-siphonage of waste into the water supply system. At a meeting recently held in Washington, D. C., committees were appointed to devise ways and means of protecting the populace against this danger.

Several years ago it was observed by noted health authorities in some of the country's most famous hospitals, in spite of all precautions, post-operative infections were occurring and water-borne diseases were spreading. Crane Co. collaborated with medical authorities, and their engineers set out to learn the cause and devise a remedy.

The first definite results were found when it was proved that a partial vacuum created in the water supply system, due to a drop in pressure, drew polluted water from waste lines into the water supply. Further research showed the condition was common; at many points fresh water lines were subject to pollution by siphonic action through the valves of such fixtures as closets, slop sinks, baths, lavatories, fountains, and aspirators.

To overcome this, Crane engineers worked out a line of vacuum breaker valves which eliminate all danger of back-siphonage.

*Crane vacuum-breaker valve which eliminates the pollution of fresh water lines by back-siphonage*

So successfully have Crane engineers applied this principle to all fixture valves where back-siphonage threatens, and extended it by raising the spouts of lavatories, baths and drinking fountains, that progressive Health Departments now insist hospitals and institutions use only such fixtures and valves as adequately guard against back-siphonage. You can see these materials at your Crane Exhibit Rooms, or get full information concerning them by writing Crane Co.

# Help mothers to cut food costs the *safe* way

*Here's a food that gives twice  
the nourishment at almost  
half the price!*

EVERYWHERE mothers are struggling with the problem of keeping the family well nourished on less money.

Yet many are not sufficiently informed to choose which foods children *must* have; which can be done without *safely*.

The child health of tomorrow depends on the advice you give today.

The Quaker Oats Company feel that they have an important contribution to make to the problem of better nutrition of children at lower cost.

Quaker Oats is rich in body building cereal protein. Served with whole milk it

provides a splendid proportion of calcium, phosphorous and iron . . . vitally important minerals when you consider their lack in the average low-cost diet. In energy value, 12 ounces of Quaker Oats equals two pounds of beef steak.

*Yet a mother can serve her children 25 nourishing Quaker Oats breakfasts for less than 10 cents.*

No other hot breakfast is more easily prepared. None more generally relished.

Advise mothers to balance budgets and balance diets too, by serving Quaker Oats regularly. All Quaker Oats packages contain from 20 to 30% more oatflakes than many millers pack.

## ON THE FOLLY OF PERPETUAL MOTION

MANY MEN who scoff at the idea of perpetual motion in a machine, try to achieve that impossibility with their own bodies. They live and work at a furious pace. They don't rest enough. They drive their jaded bodies on and on with stimulants, until, on the verge of cracking, they cross your threshold.

As you know, it is not always an easy task to get patients of this type back into the ways of sane living. For stimulants are hard to give up. But insofar as the caffein stimulant is concerned, many physicians have found that Postum can be a great help.

Postum is so delicious, so cheering that it soon makes patients forget their dependence upon caffein. Yet Postum is harmless. It is made only from sun-ripened whole wheat and bran roasted

to a golden brown, and slightly sweetened. Two and a half million families drink it regularly.

Postum comes in two forms, Postum Cereal, the kind that is boiled, and Instant Postum, made instantly in the cup. In cases of undernourishment, Instant Postum, made with milk, and served hot or iced, is a valuable addition to the diet. Postum is a product of General Foods.

*We shall be glad to send the physician who writes us, a special gift package containing a full-size package of Instant Postum, together with samples of Grape-Nuts, Post Toasties, Whole Bran, and Post's Bran Flakes. Address General Foods, Dept. PV-732, Battle Creek, Michigan. If you live in Canada, address General Foods, Limited, Dept. PV-732, Cobourg, Ontario.*

## IF THERE WERE ONLY TWO TELEPHONES IN YOUR TOWN

If there were only two telephones in your town the fortunate possessors would probably put them on pedestals in the most prominent places in their homes. Neighbors would flock to see them. Children would clamor to touch them. Bolder ones would lift the receiver to hear the magic voice—then hang up suddenly in bewilderment.

Because the telephone is in millions of homes and offices and is so much a part of our daily lives, it is not regarded with this strange awe. Yet the miracle of it is no less real. The magic of it is no less powerful.

At any hour of the day or night you can talk to almost anybody, anywhere—to far countries and to ships at sea. The first wonder is that you can talk to folks around the corner. The second wonder is that the service is so organized that you can talk to people in far away lands.

The third wonder—perhaps the greatest of all—is that telephone service is so inexpensive.

Of all things purchased, there is none that costs so little and brings to you so much convenience, security and achievement as the telephone.

# But babies *must* be fed

No matter how bad times may be the babies must be fed—with safe and wholesome food. And for no more than seven to eight cents a day any baby in America can have all the milk he needs for the best of wholesome nourishment.

"Evaporated milk is equal to pasteurized milk in all important food values; it supplies those vitamins which milk can be depended on to supply and in practically equal quantity. (Vitamin C is not present in any dependable or appreciable quantity in evaporated, pasteurized or raw milk.)"

"Evaporated milk casein curd in the stomach has a finer granular and softer texture or structure than that produced from raw or pasteurized milk; it resembles in physical structure the curd of human milk."

"The fat of evaporated milk because of the homogenization processing is more finely dispersed than the fat of ordinary milk and therefore it is more readily acted on by digestive enzymes."

"Evaporated milk is more speedily digested than raw or pasteurized milk or milk boiled only a very short time."

"Evaporated milk is considered by many pediatricians to be the best form of cow's milk for preparing the baby's formula."

"Evaporated milk is sterile and therefore is the safest milk obtainable; it cannot introduce pathogenic micro-organisms to induce diarrhea in infants."

"Evaporated milk is usually less allergic than raw or pasteurized milk."

The Committee on Food of The American Medical Association has accepted the **best form** of milk.

This extraordinary milk costs less generally than pasteurized milk—in many places no more than half as much. The tall can of Evaporated Milk, closely approximating in food value a quart of whole milk, can be bought from grocers everywhere at seven to eight cents per can.

Let us send you our free booklets "A Safer World for Babies" giving advice by a pediatrician on the care and feeding of babies—"Feeding a Family at Low Cost" a suggested week's market order, with menus, and statement of principles underlying minimum essential diet—and "More Milk—Smaller Bills" prepared in cooperation with New York welfare agencies.

# GREAT FUN, THIS PUNISHMENT

CERTAINLY, it's fun, this business of snubbing the rules of sane living. This business of over-playing and over-working. But it is punishment for tired systems, for nerves that are worn to a frazzle. Punishment for bodies that beg for rest, and get stimulation.

When you are called upon to care for victims of this mode of living, you may find it necessary to ask them to give up caffeine-containing beverages. And, as you know, you may have a tussle with them—*for that habit is a persistent one.*

In such cases, thousands of physicians have found Postum a real help. Postum is a delicious beverage that patients really enjoy—a beverage so cheering that it is easy to part from drinks that contain caffeine. And Postum is wholesome. It is made only from sun-ripened whole wheat and bran that have been roasted to a turn,

and slightly sweetened. Two and a half million families drink it regularly.

Postum comes in two forms, Postum Cereal, the kind that is boiled, and Instant Postum, made instantly in the cup. Instant Postum, made with milk, and served hot or iced, is a valuable addition to the diet in cases of under-nourishment. It is so good that it is relished even by patients who ordinarily don't like milk. Postum is a product of General Foods.

*We shall be glad to send the physician who writes us a special gift package containing a full-size package of Instant Postum, together with samples of Grape-Nuts, Grape-Nuts Flakes, Post Toasties, Whole Bran, and Post's Bran Flakes. Address General Foods, Dept. PV-832, Battle Creek, Michigan. If you live in Canada, address General Foods, Limited, Dept. PV-832, Cobourg, Ontario.*

# Protecting hospitals against water pollution in autopsy rooms . .

Fresh water lines free from pollution are of first importance to Hospital Sanitation. Crane vacuum breaker valves are essential to securing this condition.

These valves eliminate back-siphonage. They keep polluted water in the waste lines where it belongs; out of the fresh water lines where it can spread infection.

*Crane porcelain autopsy table C7020-A with vacuum breaker valve*

On all fixtures which threaten hospital sanitation, Crane Co. has made this valve standard equipment.

It is only a matter of time before all institutions will be required to take similar sanitary precautions.

Wisely managed institutions will not wait until that time. Today offers an opportunity that is without parallel

to modernize plumbing systems with fixtures equipped with vacuum breakers. For Crane Co. has reduced their price to 1913 levels and is offering to sell them under a budget plan which divides all costs of modernizing into 24 small monthly payments.

## After the first year

The many physicians who are now prescribing Evaporated Milk for babies—whether at weaning time or earlier—are giving to those babies an assurance of healthful nourishment and sturdy growth that extends far beyond the bottle days. For there need never be a weaning time from Evaporated Milk.

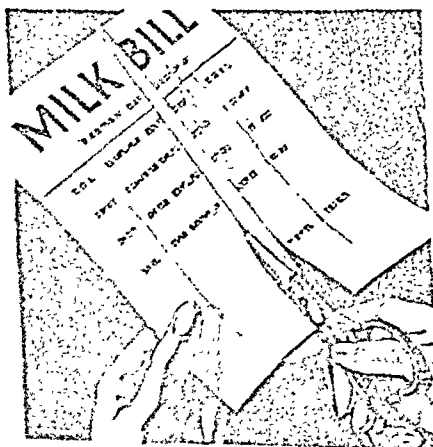

Infants who have Evaporated Milk in their bottles like the flavor of it when bottle days are over. To them it is the accepted milk flavor. They'll drink it and like it. And when they drink Evaporated Milk in later years, they'll still have pure, safe, rich milk no matter where they may be.

It is now definitely known and generally accepted that Evaporated Milk possesses all the nutritive properties that any milk provides. The anti-scorbutic vitamin is absent from Evaporated Milk as it is from pasteurized milk. But no other nutritive property of pure, fresh milk is lacking.

Evaporated Milk is not a substitute for milk. It is not a prepared food. It is milk—pure, fresh milk, concentrated, homogenized and sterilized in sealed cans. Its purity and safety are beyond question. Every drop of every can is uniformly rich in all the milk-food substances. Every drop is as surely safe as if there were no germ of disease in the world.

For babies or for children this extraordinary milk possesses the further very distinct advantage—of great importance now, important any time—of being most economical. It costs less generally than pasteurized milk—in many places no more than half as much.

Let us send you our free booklets "A Safer World for Babies" giving advice by a pediatrician on the care and feeding of babies—"Feeding a Family at Low Cost" a suggested week's market order, with menus, and statement of principles underlying minimum essential diet—and "More Milk—Smaller Bills" prepared in cooperation with New York welfare agencies.

# THE MAN WHO WISHED HE WERE TWINS

HE does the work of two men—wishes he could find time to do more. He drives himself to the limit. When Nature cries for rest, he whips tired nerves with stimulants. And soon he'll come to you, wondering, perhaps, why he is on the brink of a breakdown.

When he does arrive, you may decide that he had better dispense with a number of his habits. Caffein, perhaps, will fall under your ban. If it does, you know what a struggle he will have carrying out orders. But Postum can be a real help, if you suggest it.

There's cheering warmth in Postum . . . and aroma and flavor that are entirely delightful. Postum is so good to drink that it soon takes the place of caffein-containing beverages in a patient's affections. There are two and a half million families who wouldn't be without it.

And Postum is wholesome. It is made

only from whole wheat and bran roasted to a turn, and slightly sweetened. It contains no caffein. Nor any other stimulants.

Postum comes in two forms, Postum Cereal, the kind that is boiled, and Instant Postum, made instantly in the cup. Instant Postum, made with milk and served hot or iced, is helpful to patients who are under-nourished. It is so good that it is relished even by patients who ordinarily don't like milk. Postum is a product of General Foods.

*We shall be glad to send the physician who writes us a special gift package containing a full-size package of Instant Postum, together with samples of Grape-Nuts, Grape-Nuts Flakes, Post Toasties, Whole Bran, and Post's Bran Flakes. General Foods, Dept. PV-932, Battle Creek, Michigan. If you live in Canada, address General Foods, Ltd., Dept. PV-932, Cobourg, Ont.*

## SENTINEL OF THE NIGHT

DEEP NIGHT . . . before the first grey streaks of dawn silver the eastern sky. On a table beside the bed rests a little black instrument . . . silent, unobtrusive, seemingly inert there in the stillness. It is the *telephone*, sentinel of the night.

Ready to call a policeman at the first unexplained sound . . . ready to summon the fire department at the first ominous whiff of smoke . . . primed to rouse a physician, a nurse, or a neighbor when illness intrudes. For the wired world is at the other end, waiting for your outstretched hand and your plea: "Come quickly!" Sentinel duty, of course, is a small part of the manifold service your telephone renders. The incidents of

every-day store orders, of friendly chats; the joy and comfort of familiar voices as though from across the room; these, too, make the telephone a valued member of the family.

Behind the telephone is the nationwide organization of trained minds and hands whose ideal is to serve you in a manner as nearly perfect as is humanly possible. Seven hundred thousand stockholders—men and women like yourself—have invested their money in this system of the people and for the people.

The telephone is a vital link in the chain of modern living. It gives much in convenience and safety. It offers a wide range of usefulness. It serves you day and night.

# In all extremes

ON the hottest and most humid summer day or in below-zero weather—in the most congested city districts or in remote villages and camps—Evaporated Milk comes from its sealed container as sweet as when the fresh milk left the farm—as safe as if there were no germ of disease in the world.

For babies and children, at home or traveling, this extraordinary milk is always readily available and removes all the milk hazard of extremes in temperature. Consider these well-proven and accepted qualities:

- 1 *Uniform richness in food content.*
- 2 *Complete and assured freedom from any germ or bacterial life.*
- 3 *Ready digestibility closely comparable to that of human milk.*

THROUGH more than ten years, the Evaporated Milk Association has fostered scientific research which has established beyond question the nutritional qualities of Evaporated Milk. Many specialists have conducted practical tests with infants under their care. The results have been impressive in these important respects—absence of discomfort, digestive disturbance or illness—the presence of healthful, normal growth and development.

EVAPORATED MILK is not a prepared food. It is not a proprietary article. It is pure, fresh milk, concentrated, homogenized and sterilized in sealed containers. It is always "soft curd" milk—the curds as soft and flocculent as those from human milk. The fat globules, broken into tiny particles by homogenization, are more quickly and readily digested. From neither curds nor fat does discomfort or disturbance come to babies who have Evaporated Milk.

It is important to note, in these times, that Evaporated Milk costs less generally than ordinary milk—in many places no more than half as much.

LET us send you our free booklets "A Safer World for Babies" giving advice by a pediatrician on the care and feeding of babies—"Feeding a Family at Low Cost" a suggested week's market order, with menus, and statement of principles underlying minimum essential diet—and "More Milk—Smaller Bills" prepared in cooperation with New York welfare agencies.

# HE DIDN'T WAKE UP FOR FORTY YEARS

HE FIGURED that health was a matter of accident—either you had it, or you didn't. So far as the rules of sane living are concerned, he's been sound asleep for forty years. He's abused himself with too much work and worry—too much dependence on stimulants when his own strength failed. And he wakes up—a patient, and a problem.

The habits he's been nursing for years have a hold on him—that caffeine habit especially. You may have difficulty in making up *his* mind to avoid drinks that contain caffeine, if you should deem it necessary. Postum, however, can simplify this difficulty.

Postum is a delicious, fragrant drink that makes it easy to give up caffeine-containing beverages. It is so good that forbidden drinks are soon forgotten. So good, indeed, that two and a half million families enjoy it regularly. Postum is made only

from sun-ripened whole wheat and bran roasted to a turn, and slightly sweetened. It contains no stimulants of any kind.

Postum comes in two forms, Postum Cereal, the kind that is boiled, and Instant Postum, made instantly in the cup. Instant Postum, made with milk and served hot or iced, is very helpful to patients who are under-nourished. It is so good that it is relished even by patients who ordinarily don't like milk. Postum is a product of General Foods.

# Crane Co. has eliminated the greatest expense in building hydrotherapeutic departments

THE greatest expense connected with building a hydrotherapeutic department is the easiest to avoid. It is the cost of experimenting with materials and layouts. Crane Co. has already done this for you.

Years of research, months of trial form the background of every fixture, every plan in this important branch of Crane service to hospitals.

What this means can best be illustrated by examining a Crane fixture; the C 6232-A continuous flow bath for example. This bath is 6' 6" long, 33" wide, and permits a water depth of 18". In it the patient can lie at ease, supported by a canvas cradle. Its special bell supply is located so that the water will be kept in constant circulation and at a uniform temperature. Back siphonage is guarded against by a vacuum breaker. To protect the patient against chilling and scalding an electric thermometer alarm lights a red incandescent bulb and rings a bell whenever the water rises above or falls below the pre-determined degree of heat. This same ther-

*Crane continuous flow bath, No. C 6232-A*

mometer records a 24 hour chart of water temperature. Finally, an extra large skimming shield and a quick opening gate valve in the waste speed cleaning the bath.

Such fine and completely thought-out designing plus the experienced Crane Hospital advisory service enables you to realize the greatest economy as well as effectiveness in hydrotherapeutic departments.

# KIMBLE'S NEW BLUE LINE

## of Exax Graduated Glassware

**A**n important development — an outstanding achievement — in fine Laboratory Glassware is offered to the scientific and industrial world by the Kimble Glass Company. Kimble's new "Exax" Graduated Glassware! Every calibration line and numeral filled in with a brilliant blue glass enamel,

fused-in as an integral part of the glass!

The new Blue Enamel — more durable than any material hitherto used to fill in graduation marks — is applied by exclusive Kimble process. It contrasts strongly against the crystal glass, making this new graduated ware amazingly easy to read and accurate in operation.

Every piece of Kimble Glassware is thoroughly retempered in a special lehr or annealing furnace — a safeguard against strains, weak spots and undue breakage. Each piece is tested, retested and double-checked against errors, blemishes, or imperfections.

The new Kimble Blue Exax Line fills a long-felt need for extremely accurate, easy-to-read graduated glassware that is low in cost and lasting in service. A complete line in every detail — burettes, flasks, cylinders, pipettes, etc.

Stocked by leading Laboratory Supply Houses throughout the United States and Canada.

**KIMBLE GLASS COMPANY**  
VINELAND, NEW JERSEY.

BRANCH OFFICES: — New York, 1440 Broadway; Philadelphia, 1616 Walnut Street; Boston, 131 State St.; Chicago, 23 N. Desplaines St.; Detroit, General Motors Bldg.

# He is calling You!

You are likely to think of the telephone from your individual point of view, as a convenience, as a necessity, as a means of transmitting to others your own thoughts and desires.

But your telephone is of equal importance to those who wish to get in touch with you. Right now as you are reading, someone, somewhere, may be calling you. It may be merely a friendly greeting . . . or news of importance to change the course of your life.

"Have dinner with us tomorrow." . . . The greater part of social goings and comings are maintained by telephone. "Come quickly! You are needed." . . . In crises and emergencies the telephone is indispensable. "That contract is entirely satisfactory." . . . Wheels of industry move in direct response to messages received by telephone.

In a moment your telephone may ring. It may be a call from across the street, across the continent, across the sea.

As you receive this message . . . it may be of vital importance, it may be a mere daily detail . . . you are then sharing in the benefits of that great chain of communication which links up the activities of the world.

# GOOD FORTUNE'S FOOL

**S**UCCESSFUL at everything but living, he goes blindly on. Unmercifully he drives himself to new endeavors—and to the ragged edge of a breakdown. Then he calls on stimulants to put pep into fagged body and mind.

Eventually he'll wind up in your office, asking you for health. A problem... he'll be, and well you know it. Particularly will it be difficult for him to give up the stimulants that he is so dependent upon. It is here that Postum can be helpful.

For Postum is such a delightful drink that patients don't mind when it is substituted for their regular caffeine-containing beverages. Postum's rich, full-bodied flavor fulfills the promise of goodness made by its tempting aroma.

Postum is made only of whole wheat and bran roasted to a turn and slightly sweetened. It contains no caffeine. Two

and a half million families drink it regularly—eagerly.

Postum comes in two forms, Postum Cereal, the kind that is boiled, and Instant Postum, made instantly in the cup. Instant Postum, made with milk and served hot or iced, is helpful to patients who are under-nourished. It is so good that it is relished even by patients who ordinarily don't like milk. Postum is a product of General Foods.

*We shall be glad to send the physician who writes us a special gift package containing a full-size package of Instant Postum, together with samples of Grape-Nuts, Grape-Nuts Flakes, Post Toasties, Whole Bran, and Post's Bran Flakes. General Foods, Dept. PV-1132, Battle Creek, Michigan. If you live in Canada, address General Foods, Ltd., Dept. PV-1132, Cobourg, Ont.*

# NIGHT WATCHMAN—WITHOUT PAY

**H**E KNOWS by heart the nocturnal voice of every dog in the neighborhood. He often hears the milkman make his morning rounds. Sleep . . . sleep. If *only* he could sleep.

When an individual of this type comes to you, wondering what on earth is wrong with him, Postum may be very helpful. For if you decide that he should give up caffein-containing beverages, Postum makes it a lot easier to *really give them up*.

Postum is a wonderful drink in its own right. First it tempts with a delightful, individual aroma. Then it persuades with its rich, satisfying, full-bodied flavor. And Postum contains no caffein or other stimulant. It is made only from choice whole wheat and bran roasted to a delicate, golden brown, and slightly sweetened. Two and a half

million families drink it regularly—eagerly.

Postum comes in two forms, Postum Cereal, the kind that is boiled, and Instant Postum, made instantly in the cup. Instant Postum, made with milk and served either hot or iced, is helpful to patients who are under-nourished. It is so good that it is relished even by patients who ordinarily don't like milk. Postum is a product of General Foods.

# A simpler method of draining wounds

In this Crane anti-back-siphonage Aspirator, a definite step forward has been achieved in the surgery of wound draining.

Operating on a minimum water pressure of 10 pounds, it will create a 5-inch vacuum, while on 65 pounds water

pressure it is possible to create a 29-inch vacuum.

Chief of this Aspirator's merits are its simplicity, positive action, and prevention of back-siphon-

*The Crane C7563 Aspirator safeguards water lines against the danger of pollution by back-siphonage.*

age. These are reflected in dependability, low initial and low upkeep costs, and in reduction of water-borne infections.

Complete information on this and on the complete line of Crane Hospital Plumbing Materials whose background

is an accurate knowledge of hospital requirements can be had by writing Crane Co. or visiting one of the Crane Exhibit Rooms.

## Do bottle-fed babies get enough to eat?

MANY SPECIALISTS in the care of babies have felt that bottle-fed babies do not get enough to eat—and that through no fault of the doctor or the mother, but on account of the character of the milk.

COW'S MILK, forming hard curds in the course of digestion, couldn't be given to the young baby in food strength equal to that of mother's milk. It had to be more diluted, so that the same quantity of the milk did not provide the same amount of food.

PHYSICIANS now are avoiding that trouble through the use of Evaporated Milk. It can be given in full strength because the curds are as soft and flocculent as those which form from mother's milk. It is easily and quickly digested.

EVAPORATED Milk is pure, fresh cow's milk, concentrated, homogenized and sterilized. Its outstanding qualities of superiority for babies are its uniform richness in food substance—its sure safety because it is sterilized—its ready digestibility.

LET US SEND YOU free copies of our booklets listed on the coupon.

### Cost of Sanitary Survey of Streams<sup>\*</sup>

W. L. STEVENSON, F. A. P. H. A.

*Chief Engineer, Pennsylvania Department of Health, Harrisburg, Pa.*

THE awakened public conscience as to the conservation of water resources and abatement of stream pollution is creating demands upon some state health departments to increase their activities along these lines, upon others to inaugurate such work.

Usually bureaus of engineering of health departments are not overburdened with larger appropriations than they can wisely expend. In fact, generally, great care must be used in allotting the available funds among their many present activities so as to secure the maximum possible returns in protection and promotion of the public health.

Therefore, the cost of making sanitary surveys of streams is an important matter; hence this brief contribution.

The Bureau of Engineering of the Pennsylvania Department of Health is the agent of the Sanitary Water Board in making surveys of streams:

1. To find those which are clean
2. To determine the sanitary condition of the larger streams and rivers
3. To determine and evaluate the source of pollution
4. To lay out practicable programs for sanitary improvement of whole river systems
5. To study, in more or less detail, industrial wastes which cause harmful stream pollution

For the first item (finding clean streams), technically trained men are not needed. The bureau has a corps of "Stream Surveyors" operating under a Chief of Party. It consists of 7 young men, keen to observe, trained to locate themselves in the field from maps, tactful in dealing with citizens whom they interview, and above all else, faithful

---

<sup>\*</sup> Read before the Public Health Engineering Section of the American Public Health Association at the Sixtieth Annual Meeting at Montreal, Canada, September 17, 1931.

in doing their work completely. Three of them are only summer employees. Inexpensive automobiles are provided to the number of one-half the corps, save that the Chief Surveyor has one for his own use.

They operate in the sparsely settled parts of the state. Temporary headquarters are established at some small country hotel and working from this as a center actual traverse on foot is made of all the streams in that neighborhood to search for "artificial" sources of pollution such as sewers from dwellings, overhanging privies, discharge from milk receiving stations and the like.

These data are recorded on suitable report forms and noted on field blue print maps to indicate exact location, name and address of responsible party, kind of discharge and idea of abatability.

Most of these minor pollutions are violations of rules and regulations of the Department of Health as to public health nuisances. Where the stream surveyors find such pollutions, they verbally inform the responsible party that abatement should be made, and leave a signed statement of "Advice" as to how to make abatement. A copy of this "Advice" is sent to the main office, attached to the form report on the case. At least two reinspections are made, if necessary to determine whether abatement has been effected. In this informal way innumerable abatements are attained.

Where the advice is unheeded, report is so made to the Central Office and a formal "Abatement Notice" is served by one of the department's inspectors who are enforcement officers, and if this is not complied with legal action is taken pursuant to provisions of Pennsylvania law.

The maps with crayon notations made by the stream surveyors showing those streams free from artificial pollution are first sent to the proper district engineer for review and comment, then come to the Central Office, where they are carefully examined, the miles of clean streams measured, and then submitted to the Sanitary Water Board which thereupon formally designates the clean streams as Class "A." Every possible effort is made thereafter to keep them in that wholesome state. For instance, should a summer hotel be erected on the catchment area of a Class "A" stream, nothing less than complete sewage treatment would be considered or approved by the Sanitary Water Board.

As this work progresses the aggregate mileage of Class "A" streams in Pennsylvania is annually increasing through abatement of these minor pollutions.

The salaries of the Stream Survey Corps total \$7,400 a year, for both full-time and summer-time employees. Their living and travel

expenses in the field are paid, including automobile costs, and amount to about \$8,000 a year. The total operating cost of the corps is, therefore, about \$15,400 a year. Allowing about 20 per cent deduction from this total cost for time spent by stream surveyors on special detached service the net cost of the Stream Survey Corps while on regular duty is about \$11,500 a year, and about 3,500 miles of stream can be so surveyed each year. Therefore, it costs about \$3.30 per mile of stream, including reinspection for abatements as well as the not inconsequential education of the public which is an important activity of the Stream Survey Corps.

For sanitary surveys of the larger streams and rivers mobile laboratories are used by chemical engineers. Each laboratory is equipped to do dissolved oxygen, 5 days oxygen demand at 20° C., alkalinity or acidity and pH determinations. A new mobile laboratory is also being equipped for bacteriological work including total number of bacteria at 37° C. and presumptive *B. coli* tests.

In the earlier scientific stream studies the large heavy laboratories were driven as near as possible to the sampling point. Experience showed this to be generally undesirable because of difficulties in driving the heavy laboratory over poor dirt roads and lanes leading from the main paved highway down to the river banks. The present practice is to establish temporary headquarters for the mobile laboratory in some town centrally located to the stretch of river under examination and for the engineer to collect samples of the river water using a small inexpensive automobile as a "feeder car."

Automatic gauging stations are established on the river so that rate of flow is known at sampling times. This allows scientific comparison to be made of analyses taken at known different river stages. Sampling is done during the low flows of warm weather, except in cases of streams receiving acid coal mine drainage in which the degree of alkalinity or acidity is the dominant feature. At reasonable stream stages such work can continue nearly all year.

On wide rivers cross-section studies are made because of the influence of tributaries, and in places where heavier pollution is on one side of the stream than the other.

Sampling stations are established above known major discharges and at places below where it is deemed that the discharge has become reasonably diffused in the river water. Also sampling stations are established at the mouth of major tributaries in order to determine whether they are harmful or refreshing influences to the main river. Later similar work is extended up the tributaries which are found to be harming the main stream.

At high river stage and during cool weather the chemical engineers with their mobile laboratories study industrial wastes discharged into the stream. A basic policy in such study is always to endeavor to reach the highest possible official at the factory, explain that the purpose of the survey is to determine scientifically the sanitary condition of the stream, evaluate the sources of pollution, and find reasonable and practicable ways and means for improving the sanitary quality of the river.

In the earlier studies of individual industrial wastes the responsible executives were informed that the survey was not being made to gather information for prosecution and that if access to the factory were granted and the desired information furnished, the data so collected would be for the exclusive use of the state authorities. Such executives of industrial concerns were given a copy of the analytical report bearing a signed statement that the report was for the "exclusive use of the Sanitary Water Board."

This policy made possible the study of industrial wastes unmixed and at their points of origin in factories, where otherwise this would have been difficult, if not impossible to accomplish. The reputation of the Sanitary Water Board and its agents for "square dealing" has become so well known in Pennsylvania that it is now rarely necessary to go through the more or less cumbersome formality of officially guaranteeing confidential treatment of information secured within industrial establishments and, furthermore, the executives of practically all industrial establishments now recognize that, in view of present-day sentiment of the public and governmental agencies, it is unwise to attempt to conceal information concerning their waste water discharges.

No effort is made to measure the rate of flow or sample and analyze municipal sewage. Its load upon the stream is determined by estimating the human population connected to the sewer system and adding thereto the industrial wastes admitted to the sewers converted into equivalent human sewage by computation of B. O. D. figures.

Upon the completion of such a survey diagrams are prepared showing the average dissolved oxygen and oxygen demand in p.p.m. at each station; also by symbol maximum and minimum observations. The difference shows oxygen balance. Per cent saturation dissolved oxygen, alkalinity or acidity, bacteria, etc., are also platted.

On other diagrams the pollution loads producing these conditions are shown by ordinates to a scale of human sewage to which B. O. D. of organic industrial wastes are converted by the factor 0.22 lb. oxygen demand per diem per capita.

These diagrams are used by the executive engineer of the bureau in recommending degree of treatment of municipal sewage indicated as needed to maintain a sanitary condition of the river fit and suitable for its present and probable future public uses.

They are also used in negotiating with the parties responsible for harmful industrial waste pollution, always first visiting the concern which the diagram shows to be the cause of the heaviest load on the stream or the most harmful, as for instance in proximity to a water works intake.

The salaries and expenses of the chemical engineers and their assistants vary, and hence only aggregate figures can be given.

The records show that salaries, expense accounts, maintenance of mobile laboratories and feeder cars, and other incidental expenses in this field work, exclusive of the salary and expenses of the executive and district engineers engaged in negotiations, have cost about \$30,000 for doing work such as described above in an average working year.

Some of the scientific studies are of heavily polluted streams in densely populated and highly industrialized districts, whereas others concern problems involving only a few sources of pollution affecting an otherwise clean stream, and it would be obviously unfair to attempt to compare the costs of surveying equal lengths of such widely different streams. Again, the activities of one year may be centered almost entirely on streams where the problem is very complicated and progress slow whereas in another year the surveys conducted may be largely of streams where results can be secured with less effort and in shorter time. Then too, conditions of stream flow in a given year may not be favorable to scientific surveys and much time may be lost due to interruption of traverse studies by repeated rises in stream stage. However, it is roughly estimated that in an average year of actual field work in scientific stream surveys, including studies of industrial wastes and preliminary negotiations relative thereto, about 300 miles of main stream can be covered. This indicates, as qualified above, an approximate cost of \$100 per mile of stream.

It must be borne in mind that a river once surveyed is not by any means a permanently completed job, and that the real success in accomplishing improvement in the sanitary condition of streams is only obtainable by eternal vigilance and repeated surveys. Sewage treatment works become overloaded, industrial waste treatment works may be neglected, new industries may be established, and new methods of waste treatment may be developed which are applicable to previously unsolved problems. As a matter of fact, it has been found necessary, once a study of a large river in a heavily industrialized territory has

been undertaken, to leave one or more men permanently assigned to each project for constant follow-up.

The population of Pennsylvania is about 10 millions; there are nearly 1,000 municipalities more or less sewered and over 2,500 industrial places discharging waste waters. The aggregate length of streams in the state is about 100,000 miles.

For the biennium beginning June 1, 1931, there is available in Pennsylvania for work incident to public sewerage, industrial wastes and sanitary conservation of water resources about \$330,000. Of this, \$50,000 is a special appropriation to the Sanitary Water Board for a salinity survey of the tidal estuary of the Delaware River, \$225,000 to the board for its general work, and the remainder is from the allotment to the Bureau of Engineering from the appropriation to the Department of Health.

---

## Immunization

THE address of Professor Major Greenwood, in opening the section of Pathology at the annual meeting of the British Medical Association, carried forward the work on experimental epidemiology, with which the names of Topley and Greenwood are associated. It brings out two points: first, active immunization is of more importance than primary selection in resisting infection; and, second, the immunity conferred by virus diseases is different (at all events in intensity) from that conferred by bacterial diseases. Both of these propositions have substantial clinical backing.

The safety of any individual in an infective environment depends upon many factors, three of which are personal: initial "strength," immunity produced by contact, and immunity produced artificially. The first is the weakest, the second the strongest. In no case is resistance absolute. The nearest approach to absolute immunity would appear to be a preliminary clinical reaction followed by continuous, somewhat severe, exposure. We should imagine a fever nurse who had had diphtheria to have the maximum possible resistance to a second attack of that disease, yet it is possible even for her to die from it.

Light is also thrown on the value of pre-immunization. Here clinical and experimental work are in complete agreement; immunization tides over a difficult or particularly dangerous period; its effect is not permanent. Diphtheria immunization carries children over the dangerous age of 1 to 7; more than that it probably cannot do, and, generally, no more than that is requisite.—The Difference Between an Epidemic of One Disease and That of Another, *Med. Off.*, Oct. 24, 1931, p. 177.

# Diphtheria Toxin-Antitoxin and Toxoid\*

## A COMPARISON

WILLIAM H. PARK, M. D., F. A. P. H. A., AND  
MAY C. SCHRODER, M. D.

*Bureau of Laboratories, Department of Health, New York, N. Y.*

THESE two preparations, toxin-antitoxin and toxoid, are now being widely used for immunization of infants and young children against diphtheria. Toxin-antitoxin has been longest in use. Behring was the first to employ it experimentally as an immunizing injection in man. His preparation was the undiluted toxic broth with its toxin nearly neutralized by antitoxin. He never gave a clear explanation of how he prepared and standardized it. The breaking out of the war delayed the practical utilization of toxin-antitoxin in Europe.

Park and Zingher were the first to realize that by using the Schick test to determine the susceptibility of the children, and a retest to note the changes in reaction, we could study the immunizing effect of toxin-antitoxin injections in human beings. We demonstrated that immunity developed in about 85 per cent of those receiving 3 injections of our 3 L + preparation at intervals of 1 week, and by 1917 we realized that it lasted in the great majority of cases for at least several years. We also tried giving it at intervals of 2 weeks, but the results were only moderately better. Schroder followed the Schick reaction in the immunized children for a longer time and in 1925 found that the period of immunity extended to 10 years for at least 80 per cent of them. These were New York City children. As a rule the same children were not retested in order to avoid the possibility of the Schick test adding its immunizing effect. The long duration of immunization might have been due in some to the added immunizing effect of repeated infection from carriers.

In 1918 we began the serious attempt to immunize the whole child population of New York City. This earlier work was concerned mostly with children of school age, as most parents were not yet willing to have the injections given to the babies and very young children. We noted that in a small percentage of the children the injection gave

---

\* Read at a Special Session on Toxoid Immunization of the American Public Health Association at the Sixtieth Annual Meeting at Montreal, Canada, September 15, 1931.

quite a severe local reaction. To lessen this, we tried diluting the toxin before adding the antitoxin, and found that when as little as 0.1 L + dose of toxin was given in an injection, the immunizing effect was as good as when a 3 to 6 L + dose was used. Smaller amounts of toxin were less immunizing. The most important point is that the toxin-antitoxin to have its maximum effect has to have such a toxicity that a human dose kills a 250 gm. guinea pig in about 4 weeks. With decreasing toxicity the immunizing effect is gradually diminished.

This new preparation gave much less local reaction in children of school age, since this reaction was due, not so much to the specific toxin as to the other elements, especially the dissolved bacillus substance. It was found that even when the toxin-antitoxin was stored in good glass and kept cool the product became gradually somewhat less toxic. The reverse never happened with the 0.1 L + preparation except when it was frozen and then the increase in toxicity was not sufficient to be in the least dangerous. This characteristic of becoming less toxic is a real drawback, because many commercial preparations suffer this during transportation and the period of storage, and when this happens, 3 injections may cause only 50 to 75 per cent of the children to change from a Schick positive to a Schick negative state, instead of the expected average of about 80 per cent.

When toxin-antitoxin is accurately standardized, a full dose, injected just under the skin of the anterior surface of the arm, acts both as an immunizing injection and as a substitute for the Schick test. The result in the older children is not quite so accurate an index of immunity as that from the Schick test, but the error is on the safe side. This slight difference is due to the fact that a dose of suitable toxin-antitoxin is a little more toxic than the Schick test dose, and also to occasional nonspecific protein reactions. We have found that this use of toxin-antitoxin is a very valuable help among the school children of New York City, since without using the Schick test we are enabled to save fully 50 per cent of them from the second and third injections, as they are shown by their negative reactions to be immune. The readings are not made until the 5th or 6th day, to allow, in most cases, for the disappearance of the pseudo-reactions, which are more pronounced than with the Schick test. The 6th day is also a suitable time for the second injection in those who require it.

The possible objection, when horse antitoxin was used, that the approximately 0.001 c.c. of horse antitoxin in the immunizing dose sensitizes the injected children to later injections of therapeutic doses of an antiserum from the horse, has been removed by substituting antitoxin from the goat. We are convinced that the fear of sensitization

was greatly exaggerated, but it was wise to substitute goat antitoxin to remove any objection. This preparation of toxin-antitoxin is used generally in the United States and has given satisfaction. In New York City alone, during the past 15 years, more than 500,000 school children have been given toxin-antitoxin, and during the past 2½ years, owing to an intensive drive to stamp out diphtheria, inaugurated by the Commissioner of Health, Dr. Wynne, more than 250,000 infants and preschool children have received it. Deaths from diphtheria in New York City during 1930 were only 198 against 416 for 1929, and 800 for 1920. The figures for the first 8 months of 1931 are even better than those of 1930. During this time, the population has considerably increased. All this immunization work was performed without any accident.

Only 4 serious accidents have occurred from toxin-antitoxin injections in other cities of the world, and these would have happened just as readily if toxoid had been used. The first took place in the United States and resulted from the sending by mistake of a proved overtotoxic preparation. The second and third happened in Austria and Russia and were caused by the accidental distribution and injection of a diluted diphtheria toxin for toxin-antitoxin; while the fourth occurred in Australia, due to the use of a toxin-antitoxin preparation which had no antiseptic in it and which was stored in large bottles. The contents of one of the bottles after having been opened several times became contaminated by virulent staphylococci.

Within recent years, efforts have been made by bacteriologists to obtain a better preparation than toxin-antitoxin. Park, Zingher and Schroder stated in 1924 that a toxin which had been changed to toxoid by long standing gave remarkably good immunizing results, though the marked pseudo-reactions occasionally caused by it made it less desirable, in their opinion, for school children who made the majority of those being immunized, than the new preparation of toxin-antitoxin. Glenny and his associates, by the use of formalin, reduced toxin to a slightly toxic toxoid, and found this, when its remaining toxicity was partially neutralized by antitoxin, an excellent immunizing agent. Like toxin-antitoxin, the toxoid was diluted and gave less reaction than undiluted toxoid.

The best immunizing material now in use is, however, the *non-toxic* diphtheria toxoid which Ramon developed. He adopted the suggestions of Glenny as to the use of formalin, and of Loewenstein of Vienna as to the value of non-toxic toxoid in tetanus. He was able also to prepare a stronger toxin, and therefore toxoid, than had previously been prepared. Starting with a highly potent toxin, he reduces

its toxicity by the addition of formalin and its storage at 37° C. until it is practically non-toxic. The greater the number of L + doses in the original toxin, the better the immunizing effect of the toxoid. With toxoid sent us by Ramon, or made by Povitzky in our laboratory, we have obtained no greater pseudo-reaction from an intramuscular injection of 0.5 c.c. in little children than from the equivalent dose of 1 c.c. of toxin-antitoxin, and but little more from 1 c.c. injections, but in school children the toxoid preparations produce on the average somewhat more marked reactions than do 1 c.c. injections of toxin-antitoxin.

The immunizing effects of our best toxoid have been better than from the best properly standardized toxin-antitoxin. We have therefore recently adopted the toxoid (Ramon) for the children of pre-school age in New York City, but continue to use toxin-antitoxin for the school children and for such adults, as for instance, nurses, who require it. We may soon employ the toxoid entirely, especially, if we are able to reduce the substances in it which cause pseudo-reactions.

We have also recently tried out the inunction of toxoid mixed with lanolin (Loewenstein) and have obtained a change from a positive to a negative Schick reaction in about 70 per cent of the children on whom it was used. The 4 or 5 rubbings were made at weekly intervals. This method has certain advantages in cases where the mothers object to the use of the needle and in institutions where a nurse can apply it to the children as they enter. The ointment should be thoroughly rubbed into the skin. For general use it is more time consuming and less effective than the subcutaneous or intramuscular injection of toxin-antitoxin or toxoid.

#### INCREASE OF THE POTENCY OF DIPHTHERIA TOXOID THROUGH THE ADDITION OF ALUM

Two years ago, Glenny, working under the direction of O'Brien, found that the addition of sufficient alum to the toxoid to make a 0.2 to 0.5 per cent solution increased appreciably its power to develop antitoxin when injected in horses. We tried his methods with good results. It occurred to us that toxoid containing alum might be advantageously used in infants and children. Schroder injected about 100 children last spring with very favorable results. A report of this was made by one of us at the international meeting of the Microbiological Society at Paris last June. O'Brien told me that they had also tried it in a few children with favorable results. During the past 10 months, Schroder and Blum have injected additional children, and we have made a comparison of the results following the use of toxin-

TABLE I

A COMPARISON OF THE IMMUNIZING EFFECT OF DIPHTHERIA TOXOID, TOXOID PLUS ALUM AND TOXIN-ANTITOXIN IN GUINEA PIGS

Fraction of 1 c.c. Given and Number of Doses	Average Number of Minimal Fatal Doses Neutralized in Guinea Pigs After 1, 2 and 3 Doses of			
	Toxin-Antitoxin	Toxin-Antitoxin Alum	Toxoid	Toxoid and Alum
1/16	1.5	1.5	3	3
1/16, 1/16	3.0	5.0	6	15
1/16, 1/16, 1/16	5.0	15.0	40	60
1/8	1.5	1.5	5	10
1/8, 1/8	3.0	4.0	25	80
1/8, 1/8, 1/8	15.0	25.0	30 +	90 +
1/4	2.0	3.0	10	30
1/2	2.0	3.0	50	80
Total doses neutralized by 8 guinea pigs	33.0	58.0	169 +	368 +

Injections given at intervals of 1 week. Retests done at the end of 2 months. Note the much greater number of fatal doses neutralized by the guinea pigs receiving toxoid, especially by those receiving toxoid plus alum.

TABLE II

THE INCREASED EFFECT OF GIVING A DEFINITE QUANTITY OF TOXOID IN DIVIDED DOSES RATHER THAN IN A SINGLE ONE

	Number of m.l.d. overcome by guinea pig
A single dose of 1/2 c.c. of toxoid plus alum	80
A single dose of 1/4 c.c. of toxoid plus alum	30
Two doses of 1/8 c.c. with interval of 1 week	80
A single dose of 1/2 c.c. of toxoid	50
A single dose of 1/4 c.c. of toxoid	10
Two doses of 1/8 c.c. with interval of 1 week	20
Three doses of 1/16 c.c. with intervals of 1 week	40

antitoxin, toxoid, and toxoid with alum, in the children living in institutions. By dividing them into similar groups and giving children of similar age the injections, we felt we might obtain valuable information. Finally Welton, who has charge of our Otisville branch laboratory, injected some 500 guinea pigs with one or other of the 3 preparations. The results of these tests in children and in guinea pigs are shown in Tables I to VI.

#### DOSAGE OF TOXIN-ANTITOXIN

The almost universal custom is to give 3 injections of 1 c.c. each. A few have advised 4 or even 5 injections. More than 3 are hardly necessary, if properly prepared and preserved preparations are used. In 149 young children in which 1 c.c. of a well tested preparation was

Pigs at time of toxin injections weighed from 700 to 900 gm.

The difference shown in these two sets of guinea pigs is very slight.

recently injected by us we obtained 90 per cent of success. With over-neutralized preparations others have obtained at times as little as 50 per cent of immunization.

#### DOSAGE OF TOXOID

The potency of toxoid depends on the number of antigenic units contained in a specified amount. These can be approximately determined by the L + doses of the original toxin or by the flocculation units of the toxoid when ready for use. A good preparation and one which should be produced by all biological laboratories contains at least 8 antigenic or flocculation units per c.c. A department of health

49	1/8		1/8	1/8	150	**

\* Destroyed 8/27/31 because of necrosis at site of toxin injection.

\*\* Still living and healthy, discharged.

Pigs at beginning of immunization weighed from 260 to 300 gm.

Pigs at time of toxin injections weighed from 700 to 900 gm.

The guinea pigs having a 2-weeks interval certainly show somewhat more resistance to the toxin.

TABLE V

A COMPARISON OF THE IMMUNIZING POWER OF TOXOID WITH AND WITHOUT THE ADDITION OF ALUM IN INFANTS AND YOUNG CHILDREN LIVING IN HOME FOR HEBREW INFANTS  
THREE INJECTIONS GIVEN AT INTERVALS OF 1 WEEK

	No. of Children 2 Mos. to 2 Yrs.	Number Immun- ized	Per cent Immun- ized	No. of Children 2 to 4 Yrs.	Number Immun- ized	Per cent Immun- ized
Toxoid 1/2 c.c.....	49	44	89.8	33	31	94
Toxoid with alum 1/2 c.c.....	35	34	97	21	21	100
Toxoid with alum 1/8 c.c.....	43	41	95	13	13	100
Filtrate of Toxoid plus alum 1/2 c.c.....	25	0	100	8	0	100

TABLE VI

A COMPARISON OF DIPHTHERIA TOXIN-ANTITOXIN, TOXOID AND TOXOID WITH THE ADDITION OF 0.2 PER CENT OF ALUM AS AN IMMUNIZING AGENT IN CHILDREN.\* THREE INJECTIONS OF 1 C.C. OF TOXIN-ANTITOXIN AND 0.5 C.C. OF TOXOID WERE GIVEN.

THE INJECTIONS WERE GIVEN AT INTERVALS OF 1 WEEK

Children from 5 to 14 years of age

Immunizing Substance	No. Children	No. Immunized	Per cent Immunized
Diphtheria Toxoid (not toxic)	243	228	93.7
Diphtheria Toxoid (plus alum)	112	110	98.2
Diphtheria Toxin-antitoxin	149	132	90.0

\* The children the results of whose immunization are given in the above tables were cared for in 7 institutions. In order to attempt to make the comparison an accurate one, we selected an equal number of children from each institution for immunization by each of the substances. The children were also of similar age groups ranging from 2 to 14 years.

These were all excellent preparations. The toxoid plus alum gave the best results and the simple toxoid the next.

should know that a toxoid supplied by it is of at least this potency. If the toxoid is diluted it should contain at least 4 antigenic units in the dose advised. Such a toxoid is certainly more potent than toxin-antitoxin. Many believe that 2 injections of such toxoid are sufficient. With 3 injections of 0.5 c.c. each, Tables V and VI, we obtained about 94 per cent of successful results. Volk, of Pontiac, using our preparation, but giving only 2 injections of 0.5 c.c. each, obtained only 83.8 per cent in 246 school children. The retests were made at the end of 8 months. Of the children 23 received only 1 injection, and in these only 47 per cent of success was obtained at the end of 2 months and 63.5 per cent at the end of 8 months. It seems, therefore, that 3 doses are desirable if the dose is limited to 0.5 c.c. With 0.5 c.c. and 1 c.c., a somewhat higher percentage of immunization would be obtained, and even higher with 2 doses of 1 c.c. each; but with these there would be occasionally annoying but not serious reactions. Each person must weigh these facts and decide as to whether the possibility of the increased local reaction is a hindrance to the larger dose. It is important that health officials get the most potent preparations available.

#### MOST DESIRABLE AGE FOR IMMUNIZATION

All are agreed that we wish to treat the children at the earliest suitable age. We found some years ago that infants within a few days of birth did not respond well to injections of toxin-antitoxin. Approximately 2,000 infants were given the first injections on the 2d or 3d day after birth, and in addition 2 more at weekly intervals. There was practically no local or constitutional reaction to the injections, but when 100 of them were retested at the end of 1 year the immunization

was found to be quite disappointing. Recently Schroder has injected groups at ages of 1 month, 2 to 12 months, and over 1 year. With toxin-antitoxin her results were as follows:

No. of Infants	Age when Treated	Age when Retested	Results % Immunized
12	1 month	9 to 11 mos.	75
11	3-7 months	9 to 20 mos.	90
10	1 year	1.5 to 3 yrs.	90
4	1 year (toxoid)	17 months	100

These results taken together with those given me by Blum and shown in Table V, suggest that at 3 months or after, babies are suitable for immunization, so far as their immunity response is concerned. As to the most suitable age, other factors are of importance. In cities the new-born babies are usually immune through the transfer to them before birth of antitoxin from their mothers, while in the country the majority are susceptible. This passive antitoxic immunity lasts 6 to 12 months. For this reason the age chosen in cities as the desirable one is usually 6 to 9 months, while in the country it is usually 6 months. Another reason for waiting until the babies are at least 6 months of age is that very young infants are more apt to suffer from intestinal and other disturbances. Fortunately the earlier in life the toxin-antitoxin or toxoid is given, the less the annoyance—in fact in babies under 2 years an intramuscular injection of toxoid is not usually followed by any appreciable reaction. The toxoid gives on the average a local reaction 25 per cent more severe than does the toxin-antitoxin. Deep intramuscular injections give much less frequent and severe local reactions than subcutaneous ones.

We may sum up as follows: Non-toxic diphtheria toxoid or antitoxin is undoubtedly the best preparation for young children and probably for older ones because it is the most potent and stable immunizing agent. Suitable underneutralized toxin-antitoxin is however an efficient preparation and is only a little less immunizing than toxoid, and it has the advantage of causing less nonspecific reactions in older children. It is to be remembered that in most toxin-antitoxin preparations, the "toxin" is really mostly toxoid, since the toxin has been kept for a year or more. This allows it to become more stable and more efficient. It is difficult to decide which method should be preferred for older children. Each has its advantages. The use of toxoid mixed with lanolin, and rubbed into the skin has a distinct place, as for example, for children in institutions or in cases in which there are objections to the use of the "needle." Alum 0.1 or 0.2 per cent,

added to the toxoid adds to its immunizing power, as is also the case when it is added to toxin-antitoxin, only then to a much less extent.

It is of the greatest importance that the toxoid be made from highly potent toxin and that the antigenic units should be stated on the containers. If it is diluted, this should be stated on the label. Toxin-antitoxin should be properly standardized and have the desired toxicity. In large cities such as New York we find toxin-antitoxin has an advantage, in older children, for the injection acts not only as an immunizing dose, and gives on the average less local reaction, but because it is also a substitute for the Schick test. The exclusion of the negatively reacting children cuts down the number of later injections. For the second and third injections in these older children, either toxin-antitoxin or toxoid may be used.

A Schick retest 3 to 4 months after making the immunizing injections is always desirable but not essential, for only in this way can we be absolutely sure that the desired effect has been obtained. The tables here present some of the evidence upon which our opinions were formed.

NOTE: A part of the expense of this investigation was provided by the Committee on Administrative Practice of the American Public Health Association from an appropriation made to it by the Commonwealth Fund.

---

## Premiums to Mothers, Liège, Belgium

TO overcome the indifference of women to prenatal work and to infant health work, the municipal council of Liège, on July 1, 1931, offered premiums of 200 francs each to expectant mothers who attended regularly a prenatal health center or were examined by their own physician at least once before the end of the 6th month of pregnancy and not less than 3 times during the entire pregnancy, and who have had their infants regularly examined either at a health center or by the family physician. The premium is paid 3 months after the birth of the child.—*Oeuvre Nationale de l'Enfance, Revue Mensuelle*, Brussels, July, 1931, p. 776.

# Advantages of Toxoid in Diphtheria Prophylaxis\*

WALTER T. HARRISON

*Surgeon, U. S. Public Health Service ; National Institute of Health,  
Washington, D. C.*

ACTIVE immunization against diphtheria has developed during the past 15 years, particularly in North America, into one of the most important specific measures for the prevention of disease. Prior to the use of toxin-antitoxin mixture, smallpox vaccination was considered the most successful individual specific procedure in preventive medicine; but improvements in methods of diphtheria prophylaxis have been so great in the past few years that one can safely say that immunization against diphtheria is at least as satisfactory as vaccination against smallpox.

Since no one now-a-days questions the effectiveness of immunization campaigns on incidence of diphtheria as reflected in both cases and deaths, it is only necessary to cite in passing the experiences of Auburn, N. Y.,<sup>1,2</sup> Grand Rapids, Mich.,<sup>3</sup> and New York City,<sup>4</sup> without going into detail as to the tremendous reduction in both cases and deaths in these places, for which accurate records are available.

We are familiar with the extreme difficulty experienced by workers in reaching the most highly susceptible children for immunization, and since these children are reached with such difficulty it is important that we use the immunizing agent which will produce immunity in the greatest number of subjects injected. Toxin-antitoxin mixture and toxoid are both being used and we all wish to know which, if either, is the superior product, and the advantages and disadvantages of both.

Toxin-antitoxin mixture is made from mature toxin by adding sufficient diphtheria antitoxin so to decrease its toxicity that it may be safely injected. This delicate balance is readily attained by experienced manufacturers working with toxins and antitoxins, the values of which are accurately known.

In the beginning mixtures were made by adding antitoxin to the undiluted toxin—hence the original mixtures containing from 3 to 5 L + doses of toxin per human dose. Some of us will probably re-

---

\* Read at a Special Session on Toxoid Immunization at the American Public Health Association at the Sixtieth Annual Meeting at Montreal, Canada, September 15, 1931.

member those mixtures with the amber color of broth, which gave in older children and adults local and general reactions of the same general nature as those observed at present in the same age groups with toxoid. These mixtures containing at least 3 L + doses of toxin were used universally until 1922, when the amount of toxin was reduced 30 times, or to the present 0.1 L + mixture. The amount of unneutralized toxin, however, remains the same as in the older mixtures. This small amount of toxin has caused these allergic reactions in older children and adults practically to disappear, but in susceptible individuals the local reaction will always be encountered. In fact, the absence of local redness and swelling, with heat and tenderness, should indicate either that the patient is immune or that the mixture is not of proper toxicity. In very susceptible persons, and with strong mixtures, an occasional general reaction is encountered, with malaise, occasional vomiting, and fever.

The antitoxin used in toxin-antitoxin mixtures up to a few years ago was obtained from immunized horses, but about 1924 evidence began to accumulate that this small amount of horse serum would sensitize a considerable proportion of individuals so that severe serum sickness would follow later therapeutic injections. An occasional case of what could not be differentiated from the phenomenon of Arthus<sup>6</sup> was reported in humans.

Hooker<sup>7</sup> in 1924 showed by specific skin tests that a considerable number of patients who had received toxin-antitoxin mixtures, and no horse serum from other sources, would react to an intracutaneous injection of horse serum.

Gordon,<sup>8</sup> at the Herman Keifer Hospital in Detroit, found that the excessive number of serum reactions following scarlet fever streptococcus antitoxin was probably due to the use of horse serum in a selected group who had received sensitizing injections of toxin-antitoxin mixture. He showed that scarlet fever antitoxin was no more prone to produce unpleasant reactions than diphtheria antitoxin, when given to a child who previously had not received toxin-antitoxin mixture, or other horse serum injections. These data have led the manufacturers to substitute in toxin-antitoxin mixture antitoxin prepared by immunizing goats and sheep, which products are now widely available. In the light of our present knowledge of the sensitizing effect of minute doses of horse serum, and since effective preparations containing goat or sheep antitoxin are available, the use of horse serum toxin-antitoxin mixtures should be discouraged.

Considerable difficulty has been encountered with toxin-antitoxin mixtures with respect to the effect of freezing. Formerly freezing took

place only in the winter in cold climates, but of late the introduction and wide use of automatic refrigeration has increased our difficulties in this direction. Phenol or tricresol-preserved mixtures when frozen either lose their immunizing properties and become totally inert, or become toxic. The increase in toxicity in 0.1 L + mixtures is not sufficient to endanger life, since the original amount of toxin in this formula is not more than 3 to 7 guinea pig m.l.d.'s and a very small proportion of the original amount is released. The increased toxicity, however, is sufficient to produce unpleasant local and general reactions, and may react unfavorably upon a campaign for diphtheria prevention. These mixtures, after having been frozen and thawed, are always turbid or slightly opalescent, due to the precipitated antitoxin which does not again go into solution. Mixtures should be stored in the warmest part of the refrigerator, which usually will be found on the top shelf, at the level of the coils. Mixtures which are not crystal clear should be discarded.

The 0.1 L + mixtures are not particularly stable and should therefore be kept in the refrigerator except when actually being used. Containers which have been removed for use should be returned to the cold as soon as possible. The highly diluted toxin does not retain its activity very long at room temperature—hence, the short expiration date, 6 months from date of manufacture. A shorter date would so interfere with distribution as to render manufacture and distribution very difficult.

The immunizing value of toxin-antitoxin mixture as reported by various workers varies within rather wide limits. Some report as low as 50 per cent successful immunizations following one course of injections as measured by the Schick reaction, while others report as high as 85 per cent. Such wide variations in results by different workers may be due in some part to the tendency of mixtures to deteriorate and to variations in strength of different Schick outfits. Our own experience in the Washington schools, using mixtures at least as active as the average obtainable in the market, yielded 64 per cent successful immunizations from 3 injections. The Schick test toxin was carefully titrated and diluted each day from the bulk. From figures reported by various workers and covering all working conditions it would seem that 70 per cent successful immunizations from 3 injections would be a fair estimate of the general effectiveness of toxin-antitoxin mixture.

Diphtheria toxoid was first applied to the immunization of humans by Ramon, of the Pasteur Institute, in 1923. Ramon has named his product "Anatoxine," but English speaking countries have adopted the name "toxoid" to avoid confusion with *antitoxin*, with the probable unfortunate results which such confusion would cause.

Toxoid is prepared by adding from 3 to 4 c.c. of commercial formalin to toxin, and subjecting the mixture to a temperature of 39° to 40° C. until all toxicity is lost, which usually takes place in from 3 to 6 weeks.

The specifications for toxoid manufactured or sold in the United States are supplied by the National Institute of Health of the U. S. Public Health Service, and, roughly, are as follows:

The toxin before detoxification must contain not less than 400 m.l.d.'s, or 5 L + doses. Detoxification must be so complete that 5 human doses when injected into guinea pigs must show no signs of early or late diphtheria poisoning. The antigenic efficiency must be such that the initial human dose will immunize 80 per cent of guinea pigs in 6 weeks to such a degree that 5 m.l.d.'s of toxin will fail to kill in 10 days. This antigenic value, as measured in guinea pigs, is much greater than that of toxin-antitoxin mixture; as a matter of fact, active toxin-antitoxin mixtures are so toxic for these animals that one strong enough to immunize in 1 c.c. doses kills such a high proportion as to interfere seriously with the antigenic test.

The only protein constituents of toxoid are derived from the meat and peptone used in the broth, together with the products of metabolism of the diphtheria bacillus. It contains no serum of any kind and can, therefore, be given without fear of sensitizing to a later therapeutic dose of serum. Toxoid is very stable; the expiration date is now 18 months from the date of manufacture, and data are accumulating which may justify the extension of this period. Freezing does not seem to change it, and no physical or chemical treatment yet applied has succeeded in restoring any degree of toxicity.

As with all new products, doses of various sizes and to be given at different intervals have been suggested. Most manufacturers in the United States supply the material in packages containing 2 doses of 1.0 c.c. each and recommend an interval of from 3 to 4 weeks between doses. Since immunity depends upon the presence of diphtheria antitoxin in the blood of the subject, and as the formation of antitoxin is a slow process, better results should be obtained by using the longer interval. There is considerable experimental evidence, first presented by Glenny and Sudmersen,<sup>1</sup> which indicates that second doses given after an interval sufficient to permit a maximum reaction from the first will result in a larger response than if both doses are given with a shorter interval. In our work in Washington we found that the interval of 1 month gave very good results and was also convenient from the administrative viewpoint. The question of dosage and interval between doses will, no doubt, work itself out without difficulty as more

and more of the material is used by different workers. Two doses with the 30-day interval certainly will produce better immunity than 3 doses of toxin-antitoxin mixture given at intervals of 1 week.

The only obstacle in the way of the universal use of toxoid is the tendency to cause local and general reactions in older children. These reactions are allergic in nature and all are agreed that they are only unpleasant and never dangerous. Practically all young children give absolutely no local or general reaction, the trauma of the injection being all that can be seen. These are the individuals most susceptible to diphtheria, and it is in this group that any prophylactic measure finds its greatest usefulness. In the registration area in the United States for 1928 there were 8,263 deaths from diphtheria, of which 60 per cent were in children under 5 years of age; of this group, the 1st, 2d, and 3d years furnished the largest number of deaths. It is probably a conservative statement that the immunization of 1 child in the first 5 years of life is equal in its effect upon the diphtheria death rate to the immunization of 3 school children.

Older children and adults may be immunized with toxoid, but it is good practice to test for sensitiveness to the diphtheria proteins before the immunizing injections are begun. This test may be carried out either alone or as a control for the Schick test. A small vial of diluted toxoid 1 in 20 is furnished by the manufacturers, and 0.1 c.c. is inoculated intracutaneously, as for the Schick reaction. A local area of redness at the site of the inoculation more than  $\frac{1}{2}$  inch in diameter appearing within 3 days is interpreted as a positive reaction, and indicates that the individual may give a local or general reaction to toxoid. These persons may receive toxoid in smaller doses, the first dose ranging from 0.2 to 0.5 c.c. of the 1:20 dilution, depending upon the degree of reaction to the intracutaneous test. Subsequent doses may be given at intervals of 2 weeks, and may be doubled if the local reaction from the preceding dose was not more than  $\frac{3}{4}$  inch in diameter. Reactions up to 3 inches in diameter call for a repetition of the first dose, while more severe reactions should cause the subsequent dose to be reduced. According to Defries,<sup>9</sup> these reactors are more easily immunized than individuals who are not sensitive to the diphtheria protein.

The use of the preliminary Schick test in the older school children will enable the worker to eliminate an increasing number of immunes from the group to be immunized as the age increases, and when only 2 doses of toxoid are required as compared with 3 doses of toxin-antitoxin mixture, the worker will be required to see the subject the same number of times as when giving toxin-antitoxin mixture without preliminary test. Only a very selected group of adults will require im-

munization, those coming in close contact with cases of diphtheria—e.g., nurses, internes, and hospital attendants—and these would in the ordinary course of events be Schick-tested prior to immunization. Adults who fail to react to toxoid given intracutaneously may for purposes of immunization be considered in the same class as infants.

A surprisingly small number of controlled experiments using toxoid and toxin-antitoxin mixtures have been done. Some rather extensive work is now in progress and additional information on the relative value of the two products in actual use should soon be available.

Dick and Dick" report comparative results with toxin-antitoxin mixture and toxoid in 2 groups of 100 each, consisting mostly of adults. Five doses of toxin-antitoxin mixture, beginning with 0.5 c.c. and followed by 4 doses of 1.0 c.c. each at weekly intervals, produced a negative Schick reaction in 82 per cent after 3 months. Three doses of toxoid—the first 0.5 c.c. followed by 2 doses of 1.0 c.c. each with intervals of 3 weeks between doses 1 and 2, and 15 days between doses 2 and 3—produced 94 per cent negative Schick reactions in 6 weeks. They conclude that 3 doses of toxoid are more effective than 5 doses of toxin-antitoxin mixture.

Adams," reporting for 1926–1927 in the Canadian cities adjoining Detroit, states that among 11,000 children who had received 2 doses of toxoid the diphtheria rate was 1.55 per 1,000, while for the same period among 9,000 controls the rate was 11.44 per 1,000, and that at the ages 7 years and younger there were no reactions worth mentioning.

Ramon and Helie" state that 3 doses of toxoid—0.5, 1.0, and 1.0 c.c. with intervals of 3 weeks between the first and second doses, and 15 days between the second and third doses—will immunize more than 90 per cent children and adults.

Dr. Sumner" of the Webster Parish Health Unit, Minden, La., states that he has used toxoid in immunizing approximately 2,000 persons—2 doses each—without unfavorable reactions having been brought to his attention. These subjects ranged from 6 months to 23 years, with the greatest number included in the years 6 to 16.

Schwartz and Janne," reporting on about 14,000 children in the Milwaukee schools, retested after 3 doses of toxin-antitoxin mixture, state that from 62 to 85 per cent were negative to the Schick test; 104 preschool children immunized with toxin-antitoxin mixture prepared from sheep antitoxin showed 71 per cent Schick negative after 6 months. Ninety-three children were injected with 3 doses of toxoid, interval of 3 weeks between doses, and 1.0 c.c., with an interval of about 3 weeks between doses; the admixt were rendered Schick negative. Reactions were absent in between do and school children up to 7 years.

In Washington<sup>18</sup> we compared commercial toxin-antitoxin mixtures and commercial toxoids among school children (ages 5 to 16 years), with a few preschool children under 5 years of age. The materials used were not selected from highly antigenic lots but were chosen as routine manufacturers' samples. The Schick test material was prepared at the National Institute of Health, and the same lot was used both for the preliminary and post-Schick tests. Three doses of toxin-antitoxin mixture were given with an interval of 1 week between doses. Of 355 children tested after 104 to 195 days, 64 per cent were Schick negative. To 86 children 3 doses of toxoid were given—0.5, 1.0, and 1.0 c.c., with an interval of 1 week between doses; 92 per cent were Schick negative after 133 days. Two doses of toxoid of 1.0 c.c. each were given to 318 children, with an interval of 31 days, and after 119 days, 94 per cent were Schick negative. Seventy-two children received 2 doses of toxoid, 1.0 c.c. each with an interval of 42 days, and after 99 days all but 1 were Schick negative. Thus, of 475 children retested from 90 to 133 days after receiving toxoid, 95 per cent were Schick negative compared with 64 per cent of 355 children who received toxin-antitoxin mixture.

The preliminary Schick test was controlled with toxoid 1:20, and all children reacting to this intracutaneous test were injected with toxin-antitoxin mixture. There was therefore no local or general reaction in any child who received toxoid. It is very apparent from these figures that toxoid in 2 doses with an interval of 1 month will immunize from 20 to 30 per cent more children than will 3 doses of toxin-antitoxin mixture at weekly intervals.

Any non-toxic, non-sensitizing antigen which will give such excellent results certainly deserves the attention of the health worker, particularly since its use is followed by so little local or general disturbance in the age group which most critically needs immunization.

For children up to and including 7 years, toxoid may be used without previous test with the expectation that occasionally local reactions will occur, and very infrequently a general reaction, with headache, fever, malaise, will also be encountered. These reactions are also seen when using toxin-antitoxin mixture, but are not given so much attention, probably because a reaction of some sort is seen in all. Children over 7 may be tested for hypersusceptibility to toxoid, and those showing no reaction, or reactions less than  $\frac{1}{2}$  inch in diameter, may be given toxoid in full doses. Reactors—those giving a local reaction to the toxoid test—may be immunized with reduced doses of toxoid. As additional reports are received from workers who use toxoid in school children up to 10 or 12 years without previous test, and with only

negligible reactions in those over 8, the test for hypersusceptibility to toxoid will, no doubt, be discontinued. Until this time arrives, and pending our acquiring a greater familiarity with toxoid, we will probably continue to test the older children.

Briefly, the advantages of toxoid over toxin-antitoxin mixture may be summarized as follows:

1. It is from 20 to 30 per cent more effective, even when only 2 doses are given.
2. It contains no serum or other animal protein likely to sensitize to a later therapeutic serum injection.
3. It is absolutely without local or general reaction in practically all children under 7 years of age. Reactions in older children and adults are only unpleasant, not dangerous.
4. It contains no free toxin.
5. It is more stable, retaining its effectiveness for a longer period, and is not affected by freezing.

# Experiences with Diphtheria Toxoid in Canada<sup>\*</sup>

J. G. FITZGERALD, F. A. P. H. A., R. D. DEFRIES, F. A. P. H. A.,  
D. T. FRASER, P. J. MOLONEY, AND N. E. MCKINNON

*University of Toronto, Toronto, Canada*

VACCINATION against diphtheria in Canada, as elsewhere, is of recent origin. The employment of Ramon's anatoxin or diphtheria toxoid, as it is more widely known in the United States and Canada, dates back to 1925. Prior to that time diphtheria toxin-antitoxin mixtures had been used in a few communities in Canada, chiefly in the provinces of Ontario and Saskatchewan, on a moderate scale. Beginning in the autumn of 1924 laboratory investigations confirmed the observations of Ramon that this material was, if prepared according to the directions of Ramon himself, (a) quite innocuous, if employed in proper doses, (b) highly antigenic, and very stable ( $60^{\circ}$  C. for 3 hours), (c) quite readily prepared, if supplies of potent diphtheria toxin were available for the purpose, and (d) susceptible of reasonably satisfactory assay by means of protection tests using lethal doses of diphtheria toxin, in guinea pigs; skin tests in rabbits or guinea pigs; or by means of the flocculation test of Ramon.

This incomplete list of the advantages which toxoid possesses may be supplemented by the statement that results obtained in the vaccination of a group of young adults revealed the fact that the immunizing qualities of this prophylactic were as readily demonstrable in human beings as in experimental animals.

Upon the completion of this preliminary work, arrangements were made in a number of centers for more extended use of diphtheria toxoid prepared in the Connaught Laboratories. These further trials, notably in Hamilton, Windsor, and Brantford, Ontario, were eminently successful. Very quickly the use of toxoid spread to other parts of Canada and soon its employment upon a large scale was undertaken. This very satisfactory state of affairs has continued, and in the past 6 years sufficient toxoid for the vaccination of over 1,000,000 persons has been distributed in the Dominion.

---

<sup>\*</sup> Read at a Special Session on Toxoid Immunization of the American Public Health Association at the Sixtieth Annual Meeting at Montreal, Canada, September 15, 1931.

Since the methods of preparation and testing are well known and have previously been presented in meetings of this Association, they will not be dealt with at this time. However, certain additions to knowledge of the subject which it is believed have accrued from studies carried on in this country seem worthy of brief reference. In this category may be included the observations which have revealed the fact that it is possible to adjust the dose of toxoid so that local and general reactions of any degree of severity can practically be avoided. From the outset, insistence upon the importance of early vaccination against diphtheria has been frequently reiterated. The time of election is the preschool age period and any time after the 1st year of life seems to be suitable. Again, a thoroughly critical appraisal of the results of large scale employment of toxoid has recently been made in Canada. The results of these studies of McKinnon, Ross and Defries have recently been published. Quantitative estimation of the antigenic response to injections of toxoid has been carefully recorded by Drs. Donald T. Fraser and P. J. Moloney and Miss C. J. Fraser. It is desirable, perhaps, to deal at a little greater length with some of the points above referred to.

In the period 1921-1924 in Canada, diphtheria ranked first as a cause of death of the age group 2-14 years. It accounted for over 15 per cent, or 1 in every 7 of the deaths in that age group. The annual mortality rate per 100,000 population varied from 14 to 23. The number of deaths in a year varied from 1,281 to 2,072. In general, throughout Canada the mortality rate has been falling during the past 30 years while the morbidity rate has remained practically stationary. It is highly significant that approximately one-quarter of the cases and one-half of the deaths occur in the age group under 5 years.

When toxoid was first distributed in Canada, 2 doses were recommended. Blood titration for antitoxin content, however, showed that 2 doses produced  $1/25$  unit or more of antitoxin per c.c. of serum in 70 per cent of the vaccinated persons. This finding led to the addition of a third dose which, as will be shown, increased the percentage to a satisfactory level. Blood titration in various groups has shown that 3 doses result in the production of  $1/25$  unit of antitoxin in fully 90 per cent.

As mentioned previously, the recognition and detection of persons who might react unfavorably to toxoid was rendered possible by the introduction of the reaction test by Moloney. Further work has shown that such individuals are readily immunized without accompanying reactions if given graduated doses of toxoid.

The material used in the reaction test is suitably diluted toxoid.

One-tenth c.c. is injected into the skin of the forearm. The size and degree of the reaction in 24 to 48 hours is an index of the reaction which may be expected if prophylactic doses of toxoid are given. The test is used as a gauge of the individual's sensitivity to toxoid. For convenience the readings of these tests are recorded as 1 +, 2 +, or 3 +; 1 + signifies an area of redness no greater than 1 cm.; 2 + an area of redness greater than 1 cm., but with little or no induration; 3 + indicates definite induration at the site of the injection. Canadian experience, notably that of Burke and his colleagues, has shown that individuals who exhibit a negative, or a 1 + reading, can be given the regular dosage of toxoid without question. Those showing a 2 + reading should be given smaller doses, and the few showing a 3 + should be given a specially diluted toxoid. To facilitate the immunization of such markedly sensitive individuals, suitably diluted toxoid is now distributed in Canada. In over 30,000 children in Toronto, in whom the reaction test readings were recorded, the vast majority, 84 per cent, had no reaction or at most a very slight one. These school children were given the regular dosage without showing subsequent reaction. Five per cent of this large group showed a 2 + reading. These were given smaller doses without producing significant reactions. The readings in these 30,000 children show too that the degree of reaction to the reaction test, and therefore to toxoid, varies with age. In pre-school age children, a very small percentage showed any reaction to the test and none showed redness of any significant degree. As the child grows older and perhaps becomes sensitized by contact in a diphtherial environment, he is more likely to show reaction. Of those in the school age group of 5-14 years, 10 per cent exhibited a 3 + reading, this being confined chiefly to the older children. Our experience has also shown that those who do present reaction to the test are more readily immunized than others, so that very small doses of diluted material serve in the vast majority to bring the antitoxin content up to the requisite level.

The results of toxoid immunization can be measured in three ways:

1. By testing (Schick tests or blood titration)
2. By comparing the amount of diphtheria in a group of adequate size who have received toxoid, with the amount of diphtheria in a group of the same age distribution and living under similar conditions but not given toxoid
3. By comparing the morbidity and mortality rates in a community before and after the use of toxoid

Blood titrations before and after immunization have shown that in individuals who had less than 1/50 unit before immunization, 90 per cent had 1/25 unit or more antitoxin after receiving 3 doses of toxoid.

In the analyses of the diphtheria cases which occurred in 16,829 Toronto school children who were given 3 doses of toxoid, 0.5 c.c., 0.5 c.c. and 1 c.c. at intervals of 3 weeks, and 8,994 who were given 2 doses of toxoid, 0.5 c.c. each with a 3-weeks interval, and observed for a period from 1 to 3½ years, it has been estimated that during the period of observation, had diphtheria occurred in the treated children at the same rate as in the control group of the same age and under the same conditions of exposure, namely, that of the public school, there would have been expected 222 cases in those given 3 doses of toxoid. There were actually 23 cases reported and among these not one death occurred. This is a reduction of 90 per cent for the whole period. In the first year following immunization the reduction in diphtheria was from 95 to 100 per cent. In the 8,994 children given 2 doses, 200 cases might have been expected; 52 were reported, a reduction over the whole period of 74 per cent. An interesting parallelism between the antigenic response in individuals vaccinated with toxoid and the degree of community protection against diphtheria which resulted is evident in the above figures. The results of the assays of the serums of those given 2 doses of toxoid showed that about 70 per cent were immune and the statistical evidence indicates a reduction in diphtheria mortality in that group of 74 per cent. Furthermore the percentage of individuals immunized when 3 doses of toxoid were given, as determined by blood titrations, was 90 per cent and the reduction in diphtheria mortality in the group of Toronto school children was 90 per cent.

The results in Hamilton, with a population of 150,000, and Brantford, with a population of 18,000, may be quoted as examples of municipalities that have practically eliminated diphtheria. Other experiences such as that in Windsor might also be quoted. Data from the province of Manitoba recently presented by Dr. F. W. Jackson suggest that widespread immunization in that province is a factor which accounts for the unprecedentedly low figures of diphtheria in the past year and the first months of this year.

The efficiency and practicability of toxoid, properly prepared, as an immunizing agent against diphtheria, is established.

# Degree of Immunization from Injection of Diphtheria Toxoid\*

(a) of Different Strength Toxoids (b) at Varying Intervals (c) of Treated Toxoids

O. R. POVITZKY, M. D., DR. P. H.

*Bureau of Laboratories, Department of Health, New York, N. Y.*

BECAUSE the introduction of practical administration of diphtheria toxoid is quite recent we have not as yet arrived at a definite dosage for immunization against diphtheria. The National Institute of Health in Washington has issued definite minimum requirements for the production and administration of toxoid, namely: the original toxin should not contain less than 5 L + per c.c.; the maximum dose should not exceed 1 c.c. of the undiluted toxoid. The toxoid must protect at least 80 per cent of guinea pigs for 10 days when injected with the initial human dose against 5 m.l.d.'s.

While these requirements are a great safeguard against conversion of worthless toxins into toxoids, we are still in the dark as to the exact dosage of toxoid required for immunization. Ramon's experience has been with toxoids of at least 10 antigenic units per c.c. He obtained immunity in 95-98 per cent of cases by giving 0.5 c.c., 1.0 and 1.5 c.c. of toxoid at intervals of 3 weeks after the first and 2 weeks after the second injection. Park is giving 3 injections of 0.5 c.c. of our toxoids which also average around 10 antigenic units. Other workers report more or less favorable results describing the quantities of the toxoid administered in cubic centimeters and at different intervals, but seldom mention the strength of the toxoid. We may in time be able to decide what minimum dosage of toxoid will insure adequate immunity. But in order to define this amount the toxoids should be standardized by the number of antigenic units per c.c., and the workers should tabulate their results according to the antigenic units administered.

Fortunately we have a very effective means of establishing such a unit † in the Ramon flocculation test, Ramon<sup>1</sup> found how uniform such

\* Read at a Special Session on Toxoid Immunization of the American Public Health Association at the Sixtieth Annual Meeting at Montreal, Canada, September 15, 1931.

† Schmidt of Copenhagen suggests the unit be called "Immunizing Unit" (U.I.) in distinction from Antitoxic Unit (U.A.).

a standard could be, when he tested 11 lots of toxoids prepared in different laboratories from various parts of Europe. His results by this test agreed very closely with those of Schmidt of Copenhagen. The same results were obtained with both the French and Danish antitoxins.

#### RAMON FLOCCULATION TEST

Because many readers may not be familiar with it, the author thinks it necessary to describe briefly this important test which is gradually replacing the use of guinea pigs in immunization work in diphtheria. In 1922 Ramon of the Pasteur Institute in France introduced a practical and simple method of standardizing diphtheria toxins and antitoxins by means of the test tube.

The test is based on the previously found principle that when toxin is brought in contact with antitoxin in suitable proportions, namely, to effect a neutralization or a saturation, a reaction occurs. This manifests itself first in clouding up of the mixture, then formation of flocculi, which finally fall to the bottom, leaving the supernatant fluid clear again. The test is set up with varying amounts of antitoxin and equal amounts of toxin per tube—usually 1–4 c.c., depending on the strength of either the toxin or antitoxin. The test is kept at the water bath at 55° C. For titrating toxin or toxoid a standardized antitoxin is used; for titrating antitoxin, a standardized toxin. The first tube which shows a reaction is called the "*indicating tube*" and corresponds to the neutralized or saturated mixture. From the amounts of toxin and antitoxin which enter into this reaction, the titer of either the toxin or toxoid as to the number of antigenic or flocculating units per c.c., or of the antitoxin as to the number of antitoxic units per c.c., is calculated. No reaction occurs with an excess or too small amounts of antitoxin to effect a neutralization. But reactions do occur on either side of the *indicating* mixture later on, when the amounts of antitoxin are on the borderline for neutralization. It is therefore important to watch carefully for the *first tube* showing the reaction, because this is the *specific* reaction and usually corresponds with that in the guinea pig, as far as the L + dose or antitoxic units are concerned.

For titration of toxoids, this test is invaluable. The toxoids show the same titer by flocculation test as the original toxin, though the time for the reaction is slightly delayed. The present standard of the National Institute of Health in Washington calls for the minimum of 5 L + doses per c.c. of the original toxin. This should correspond conservatively to at least 5 antigenic or flocculating units in the resultant toxoid by the Ramon test. In examining the products from different manufacturers on the market, the author found that one toxoid showed 6.8 to 7 antigenic units; one showed 4.4 and one 4.2 antigenic units per c.c. Two (diluted) showed no antigenic units by flocculation. One (non-diluted) showed no flocculation though kept in the waterbath almost a week. It is against such variations we have to

guard. The flocculation test tells us promptly whether the toxoid conforms to the requirements from Washington as far as the value of the original toxin goes.\*

Since 1924 we have been constantly guided by the Ramon flocculation test<sup>2</sup> in all phases of toxin, toxoid, and antitoxin production work for the testing of antigenic or antitoxic units. We follow the progress of our toxins<sup>3</sup> from day to day by this test, and convert a toxin into a toxoid<sup>4</sup> only when it gives a flocculation reaction with our standard antitoxin in the proper proportions in from  $\frac{1}{2}$  to  $\frac{3}{4}$  hour. The promptness of the reaction in the freshly prepared toxin is dependent on the number of L + doses per c.c. and in the toxoid on the number of antigenic units per c.c. An antigenic unit has the ratio of 1:1 to the antitoxic unit. If, say, 11 antitoxic units produce the specific flocculation with 1 c.c. of the toxin or toxoid—1 antigenic unit is equal to 1/11 and 1 c.c. of the toxin or toxoid to 11 units. The weaker the toxin or toxoid, the more delayed the reaction. The reaction is also delayed with concentrated toxoids and it is sometimes necessary to blend it with the crude toxoid for the test and then estimate the titer. The slowness or promptness of the reaction of the antitoxin on the other hand, is not dependent on the antitoxic units, but is a characteristic of the horse, and this is maintained throughout the immunization period. It is well to keep this fact in mind in following up the progress of immunization in horses. The discrepancies between guinea pig and the Ramon test reported by different authors, including the writer, are usually due to the wrong proportions between toxin and antitoxin. Since 1925<sup>5</sup> when the characteristic of the horse as to the slowness or promptness of reaction was noticed, our results have been more reliable and specific. When a serum gives a reaction at the usual temperature with the standard toxin in 2, 3 or more hours, when it should give it in 1 hour, we know that the amounts of toxin and antitoxin are not proportionate. The test is repeated several times until the reaction is obtained within the proper time. The Ramon test, when the amounts of toxin and antitoxin are proportionate, is, in the opinion of the author, one of the most reliable we have. The reactions which occur later on either side of the indicating tube are not specific and may lead to wrong calculations.

We are guided by the Ramon test in preparing mixtures of toxoid with different percentages of alum. In the purification of toxoids

---

\* In our opinion the requirements of the National Institute of Health for the potency of the toxoid are inadequate. Toxin-antitoxin is of necessity given very cautiously and the demand for protection against 5 m.l.d's. cannot be exceeded. This is not true of toxoid and a much higher standard for protection can be required. At present the producer can ignore the initial requirements or greatly dilute a good toxoid to the minimum of antigenic units and still comply with the requirements from Washington as far as the final product is concerned.

(5) the effect of toxoid purified by precipitation with alcohol (Reiner's Method).

The solution of toxoid-antitoxin flocculi was prepared according to

the method of Ramon, Legroux and Schoen." This is a process of extracting antigen from the flocculated mixture of toxoid-antitoxin. The flocculated mixture was centrifuged, washed with physiological salt solution, again centrifuged, then dissolved in distilled water 4 times less than the original volume, and heated to 82° C. for 20 minutes.

The resulting concentrated and purified antigen (most of nitrogen is removed) is claimed by the authors to possess all the characteristics of a toxoid, namely, thermostability, irreversibility, specificity, flocculating and immunizing power, and presents dissociation phenomena in the presence of an L o dose. As will be seen from the tables, the solution of flocculi gives quite good immunity in the guinea pig though not in proportion to its antigenic units as compared with the crude toxoid. But because it gives very little reaction in the adult human, it could be used in the proper dosage as an antigenic agent in selected cases. The toxoid purified by precipitation with alcohol, gives too severe reactions in the human to be considered in its present state as a substitute for the unconcentrated toxoid.

The accompanying tables are illustrative of the results on the points discussed. Table I shows that with an equal dose of different toxoids, the degree of immunization increases with the number of antigenic units per c.c. of the toxoid. Thus toxoid 892 containing 11.6 units is far superior to toxoids 901 and 903 containing 7.6 and 5.9 units respectively. Seven weeks after the injection the guinea pigs receiving  $\frac{1}{2}$  c.c. of toxoid 892 survived 30 and 40 m.l.d.'s while only some of those injected with the others survived 15 m.l.d.'s.

Table II shows that the same dose of 901 (7.6 antigenic units per c.c.) when given in 2 and 3 portions 1 week apart confers more immunity than the single dose of 0.5 c.c. or even less (0.25 or 0.125 c.c.). The degree of immunity is still more enhanced when the same divided doses are given 3 weeks after the first and 2 weeks after the second injection.

Table III demonstrates the same principle with the stronger toxoid 892 (11.6 antigenic units) though not to the same degree as the weaker.

Table IV illustrates the degree of immunity conferred by the solution of toxoid-antitoxin flocculi. Compared to the immunity conferred by toxoid 892, which was given in 5.8, 5.8 and 7.3, totalling 18.9 antigenic units, the solution of flocculi does not show up so well with 5.5, 8.3 and 11.0, totalling 24.8 antigenic units.

Table V shows some of the dissociation phenomena of toxoid 892 (11.6 antigenic units per c.c.) and the solution of toxoid-antitoxin flocculi in different quantities in the presence of an L o dose. The results with the solution of toxoid flocculi would prove Ramon's con-

tention that this preparation has all the characteristics of toxoid.

Unfortunately we had very bad luck with guinea pigs this year. Fully three-quarters of them died of septicemia before we had a chance to test them. Still as all the animals were subjected to the same conditions, the comparisons are pretty fair. In the dissociation phenomena with toxoid and the solution of toxoid flocculi the death of the animal was rather delayed compared with the results given by Ramon. It was due probably to the fact that the L<sub>0</sub> dose was prepared with a fresh toxin and promptly flocculating antitoxin (25 minutes). When the toxoid and solution of toxoid flocculi, respectively, were added to the L<sub>0</sub> dose after standing 15 minutes a more stable union between the toxin and antitoxin might have taken place and a smaller quantity of toxin consequently liberated than when a slowly reacting antitoxin was employed. Ramon<sup>7</sup> mentions the same occurrence when he used a promptly flocculating antitoxin. These facts would prove Madsen and Schmidt's contention that a promptly flocculating antitoxin had a greater therapeutic effect than a slowly flocculating one. More work is in progress on this point.

## Cuba Honors Dr. Finlay

THE 98th Anniversary of the birth of the noted Cuban bacteriologist, Dr. Charles John Finlay, was celebrated by a ceremony under the auspices of the Department of Health of Havana on December 3. This took place in the open court of the Department's building, where a statue of Dr. Finlay was erected some years ago.

# The Preparation of Stabilized Schick Toxin\*

P. J. MOLONEY AND EDITH M. TAYLOR

*Connaught Laboratories, University of Toronto, Toronto, Canada*

HERETOFORE in carrying out the Schick test it has been necessary, on account of the instability of diphtheria toxin diluted with saline, to dilute the toxin just prior to the test. Apart from the inconvenience of this procedure, there is always the possibility of error, due either to inaccuracy in the measurement of small amounts of undiluted toxin or to improper technic in mixing the toxin and saline. Recently, however, certain diluents have been recommended the purpose of which is to increase the stability of the diluted toxin. Glenny, Pope and Waddington<sup>1</sup> showed that if borate buffered saline is used as diluent in place of the usual phenolized saline there is a marked improvement in the stability of the diluted product. Later Glenny and Waddington<sup>2</sup> found that the stability of the diluted toxin could be further increased by the addition of broth. Bunney<sup>3</sup> recommended as diluent a solution containing 2 per cent peptone, 0.8 per cent sodium chloride and 0.5 per cent phenol. His diluted toxins were entirely satisfactory from the point of view of stability. He pointed out, however, that with his stabilized toxin, reactions were in some cases more marked than was desirable. O'Brien<sup>4</sup> in a recent note stated that Glenny has found that borate buffered saline containing peptone 1-1,000 is a satisfactory diluent for Schick toxin. In a recently published paper<sup>5</sup> we have shown that diphtheria toxin diluted with saline containing borate buffer and gelatin is more stable with respect to toxicity than toxin diluted with saline containing only borate buffer.

In this paper we are reporting further results on the use of borate-gelatin-saline as a stabilizing agent for Schick toxin.

For the standardization and testing of Schick toxin we use the method which is set forth in the "British Therapeutic Substances Regulations," 1927, and also in the Canadian "Regulations under the Food and Drugs Act," 1928. By this method of standardization, Schick toxin must fulfil a toxicity requirement and an antitoxin combining requirement.

\* Read before the Laboratory Section of the American Public Health Association at the Sixtieth Annual Meeting at Montreal, Canada, September 14, 1931.

The following details, by which a test dose of Schick toxin is measured, are taken from the British Regulations.

1. Toxicity requirement: "By intracutaneous injection into normal guinea pigs, without admixture with antitoxin, 1/50 of 1 test dose must not cause, and 1/25 of 1 test dose must cause, a definite local reaction of the type known as the 'positive Schick reaction.'"

2. Antitoxin combining requirement: "By intracutaneous injection into normal guinea pigs in mixtures with different proportions of diphtheria antitoxin. One test dose mixed with 1/750 or more of a unit of antitoxin must cause no local reaction, but mixed with 1/1,250 or less of a unit of antitoxin must cause a definite local reaction of the type known as the 'positive Schick reaction.'"

Toxins which fulfil these requirements have a toxicity of about 1/50 m.l.d. per 0.1 c.c. From among 10 toxins containing 0.5 per cent phenol which had been stored for 2 years or more, 9 were found by these requirements to be suitable for the Schick test.

#### EFFECT OF VARIATIONS IN DILUENT

In Table I there is summarized the results of experiments on the effect of concentration of borate, concentration of gelatin and pH on the stability of Schick toxin. The toxin solutions used were prepared as follows: Two borate buffer solutions pH 7.9 and pH 8.5, made after the method of Sørensen, were each diluted 1-2 and 1-4 with distilled water and sodium chloride added to a concentration of 0.85 per cent. Four measured amounts of each of these 4 solutions were autoclaved, and after they had cooled, gelatin was added from a sterile 6 per cent solution in amounts to give for each concentration of borate 4 solutions containing respectively 0.08 per cent, 0.04 per cent, 0.02 per cent and 0.0 per cent of gelatin. Diphtheria toxin was then added to each of the 16 solutions in such amount that the final concentration fulfilled the Schick toxin requirements. The Schick toxins, prepared as above, were filled into nonsol vials and some of each of these we kept at 37° C., at room temperature, and in the cold room, until the tests were carried out.

The results recorded in Table I were obtained by diluting the Schick toxins 1/25 and injecting 0.1 c.c. of these dilutions intradermally into guinea pigs. The numbers represent the diameters in mm. of the resulting reactions after 48 hours.

Of the toxins which had been kept at 37° C. for 6 days, those without gelatin were atoxic at the 1/25 dilution, those containing gelatin at pH 8.5 showed a noticeable loss in toxicity, while those containing gelatin at pH 7.9 were not appreciably changed. Further within the limits tested the results showed that the toxicity of the solutions does

not depend on the concentration of borate or the concentration of gelatin.

There was no noticeable alteration in those toxins which had been kept for 6 months at room temperature or for 10 months in the cold room (8° C.).

#### STABILITY OF DIFFERENT TOXINS DILUTED TO SCHICK TOXIN CONCENTRATION

Five different phenolized (0.5 per cent) toxins which had been stored for a period of 2 years or more were each diluted to the level of Schick toxin with borate-gelatin-saline (Sørensen's borate buffer pH 8.0 diluted 1-4, sodium chloride 0.85 per cent and gelatin 0.02 per cent). These, after having been filled into glass vials, were left at

37° C. for 4 days and then tested for toxicity. The results, given in Table II, indicate that all 5 toxins were stabilized equally well.

#### EFFECT OF TRANSPORTATION

We owe the suggestion for carrying out an experiment on the effect of transportation on Schick toxin to the paper by Bunney.<sup>3</sup> A Schick toxin, made up as just described, was filled into hard and soft glass ampoules, some of which were sent by mail to various places and returned to us for testing. At no time during the shipping were the ampoules kept on ice. The results given in Table III are for the toxins contained in the soft glass ampoules. There was no significant difference due to the different types of glass.

p = pink

NOTE: We wish to thank Mrs. Paul Geerling, Dr. W. B. Johnson, Dr. A. Moschini, Dr. Manuel G. Juarequi, Dr. W. B. McClure, Rev. William K. Amyot, Dr. J. G. FitzGerald for their kind coöperation in these experiments.

The toxins were in transport during the summer months—June, July and August. The table shows that they did not lose significantly in toxicity during shipping.

#### REACTIONS IN HUMANS

Table IV gives the results of Schick tests carried out on a group of adults aged 25–35 years. The materials used were Schick toxin

diluted with saline, Schick toxin diluted with borate-saline containing gelatin, Schick toxin diluted with saline and heated, and diluted toxoid. The numbers represent the average diameters in mm. of the reactions 7 days after the injections. There is substantial agreement between the results with the regular Schick toxin and the Schick toxin containing gelatin. The agreements in readings between the 2 toxins were equally good on the preceding days. In no test which we have carried out on humans using regular Schick toxin and Schick toxin containing gelatin has there been evidence of undesirable reaction due to the gelatin.

It is worthy of note that all Schick toxins are not equally suitable for the test. Certain ones give a higher percentage of interpretable readings than others. Of 2 Schick toxins, for example, which fulfil the toxicity and antitoxin combining requirements, one may be more suitable than the other because of the greater degree in which it exhibits a fading out of reaction in immune individuals who are sensitive to diphtheria protein or other protein contained in the Schick toxin.

TABLE IV  
SEVENTH DAY READINGS OF SCHICK TESTS ON ADULTS

No. of Individuals	Antitoxin per c.c. Serum	Stabilized Schick Toxin	Schick Toxin	Heated Schick Toxin	Diluted Toxoid

1	> 1/25	12p	21p	15p	14p
1	> 1/25	14r	15p	14p	11r
1	> 1/25	16r	17p	16p	16r
1	> 1/25	8p	11p	11p	12p
1	> 1/25	10r	12r	10p	14r
1	> 1/25	5p	10p	10p	10p

## CONCLUSIONS

Evidence is presented that a 1-4 dilution of Sørensen's borate buffer pH 8.0 containing sodium chloride 0.85 per cent and gelatin 0.02 per cent is a suitable diluent for the preparation of Schick toxin.

Pellagra in the United States

AS early as 1864, Gray of New York, and Tyler of Massachusetts, each reported a case of pellagra. Sherwell of New York reported cases in 1882 and 1902. Harris of Georgia reported a case complicating hookworm disease in 1902. In 1912, Babcock, a pioneer student of pellagra in this country, from a study of the clinical records of the South Carolina State Hospital for the Insane, and from personal interviews and correspondence with practitioners, asylum authorities, and others concerned, reached the conclusion that the disease had been continuously present in South Carolina at least since 1828. He also presented information indicating that the same may be said of many other sections of the South. Searcy, the first to report pellagra in endemic form in this country, states that there had been cases present but unrecognized at the Mount Vernon (Alabama) asylum each year at least since 1901. From a superficial survey of the Peoria (Illinois) State Hospital following the diagnosis of the first case, Siler and Nichols found many cases present, and from their study of this institution they concluded that the disease had been present there without recognition for not less than four years prior to the time of their investigation. Interesting reports of the experiences of practitioners and institution officials with the disease before they knew its nature are frequently encountered in the early American literature on pellagra, and the disease in endemic form has been traced back by various observers in various sections to 1885 and beyond. . . .

The principal argument against the existence of pellagra in the South to any considerable extent prior to its general recognition in 1907-1908 is the fact that it was not so recognized. This position may appear reasonably sound when taken at face value; but there are many valid reasons why the most competent physician might have failed to recognize the disease. Few of the older American textbooks on medical subjects mention it. Such well known books as *Flint's Practice of Medicine*, published in 1866 and revised in 1880, *American Text Book of the Theory and Practice of Medicine* (1887), Musser's *Medical Diagnosis* (1896), and other standard works of that period make no reference to such a condition. In the first seven editions of Osler's *Principles and Practice of Medicine* the disease receives scant notice, the brief reference to it embodying the statement: "it has not been observed in the United States." In a later (eighth) edition of his work this author states that "it has probably been present in the South for 50 years."—*Pub. Health Rep.*, Sept. 18, 1931, pp. 2223 & 2226.

# What Can a Community Do When It Is Not Yet Ready to Establish a Mental Hygiene Clinic?\*

H. G. WEISKOTTEN, M. D.

*Dean, College of Medicine, Syracuse University, Syracuse, N. Y.*

TO ask one interested in medical education to introduce this subject and to ask one interested in nursing education to open the discussion might be interpreted as emphasizing the shortcomings of both medical and nursing education as far as mental hygiene is concerned. Were the medical and nursing profession even reasonably "mental hygiene conscious," the development of a community mental hygiene program would be greatly facilitated.

In view of the previous discussion and the many and varied factors involved, I will present the subject not at all from the theoretical or philosophical viewpoint but rather by reviewing briefly our experiences in Syracuse during the past 6 years. In September, 1925, the situation there was somewhat as follows:

There were no trained workers in family case work. There was no intelligent children's work; no intelligent child placing work. Probation work was very inadequate. Practically no genuine protective work was done. Cases were brought into court and summarily disposed of. No visiting teacher work was done. There were a part-time psychiatrist and a psychologist attached to the Board of Education, whose work, however, pertained to children referred for placement in ungraded classes.

In connection with our Free Dispensary we did have a 5-year old psychiatric clinic, which clinic received both children and adults. During the first 2 years there was neither a social worker nor any clerical help in connection with it. The psychiatrists in charge were busy practitioners serving on a part-time volunteer basis. Handicapped as they were, they were able to accomplish only a little of what we knew should be done and the clinic was failing in the fulness of its purpose

\* Read at a Joint Session of the Child Hygiene and Public Health Nursing Sections of the American Public Health Association at the Sixteenth Annual Meeting at Montreal, Canada, September 14, 1931.

both in the eyes of those responsible for its conduct and of the general profession.

In November, 1922, at the suggestion of the psychiatrist in charge, the state was persuaded to coöperate in placing a competent psychiatric social worker in this clinic, which also served as a state parole clinic. The Onondaga Health Association paid part of the salary of this worker.

By 1925, sufficient interest had been aroused to warrant the formation of the Mental Hygiene Committee in the Onondaga Health Association. Key people in the community were persuaded to accept membership on it.

We had been extremely fortunate in securing an unusually competent worker in our dispensary clinic, and according to plan she immediately became Secretary of our Mental Hygiene Committee. She made frequent reports to the committee and there rapidly developed an enthusiastic interest in her work.

Eventually the committee, desiring to expand the scope of the program, carefully surveyed the entire local situation and decided that the most promising field for development was in the public schools. The City Department of Education signified its willingness to have the Secretary of our Mental Hygiene Committee serve as a visiting teacher in one of the schools. Considerable care was exercised in selecting the school in which this demonstration should be carried on.

The following year she was relieved of her psychiatric clinic responsibilities, this work being carried on by another competent worker brought to Syracuse by the committee.

At the same time the Board of Education appointed an additional psychiatric social worker to do visiting teacher work in another of the public schools. She was selected by the Mental Hygiene Committee and at first her salary was paid by the Milbank Memorial Fund as part of the Syracuse Health Demonstration. After the first year her salary was taken over by the city.

During this whole period, in addition to reporting frequently to the Mental Hygiene Committee, these workers carried on an educational program among the school teachers and with parent-teacher groups.

A number of public meetings, addressed by men with outstanding reputations, were held. The response was gratifying. To develop public interest and understanding, during the fall and winter of 1927 and 1928, a series of 8 mental hygiene lectures was arranged and a fee of \$5 was charged for the course. Our attendance was something over 800 and the lectures netted sufficient funds to provide scholarships for summer courses for 6 local public health nurses and school teachers.

Later we ventured a 4-day institute involving 8 sessions within a period of 2 weeks, conducted by Dr. George K. Pratt of the National Committee on Mental Hygiene. The course tickets sold for \$3 and the average attendance was about 300.

In September, 1929, a psychiatric supervising nurse was appointed in connection with the generalized nursing plan of the Bureau of Nursing of our City Health Department. This, I believe, was an innovation in municipal public health nursing. This supervisor's first activity was to give the nurses an understanding of mental hygiene and methods of approach. The mental hygiene program was integrated with every other activity of the nursing service instead of being developed as a separate entity.

For several years previous the Health Department had employed a part-time psychiatrist in connection with its preschool clinics. Here the psychiatric needs of the cases, including habit training, are met both by private consultation with the mothers and in habit training classes. The mental hygiene aspect of the preschool work has become very popular, so much so in fact that it is difficult to meet the demand for this type of service.

Other agencies were stimulated by the development of our program, and in April, 1929, following a study of the local situation by Dr. C. C. Carstens, the Children's Bureau (formerly The Society for the Prevention of Cruelty to Children), was completely reorganized. A competent director and trained social case workers were brought to Syracuse and that agency is now rendering a real, high type service.

In September, 1930, 2 additional visiting teachers were appointed by the Board of Education, which is now apparently prepared to develop this work as rapidly as practicable.

During this whole period there has gradually developed throughout the community a real demand for trained social case workers with a knowledge of mental hygiene. The Community Chest and the city administration have within the past few months sponsored a study of the entire local situation by the Family Welfare Association of America. We are looking forward to a series of really worthwhile developments as a result of this study.

Early in the development of our program there was evidenced an interest on the part of several groups in the establishment of a high grade child guidance clinic in Syracuse. A special committee of the Mental Hygiene Committee was appointed to consider the matter. The state was building a psychopathic hospital as one of the units of the University Medical Center and there was much discussion in regard to the advisability of this institution, or one of the other units of

the center, assuming responsibility for such a clinic. There was also much uncertainty in regard to how far the development of the Department of Education mental hygiene program would extend. These uncertainties with the relatively great financial outlay involved in the establishment and maintenance of such a clinic have led us to defer action in regard to it. There were also those of us who were still uncertain as to whether child guidance work should be developed by psychiatrists or by psychiatrically trained pediatricians.

With the opening of the State Psychopathic Hospital in January, 1931, the psychiatric clinic was transferred from the dispensary to the new institution. Although children have been admitted to both the out-patient department and the hospital proper no effort has been made to develop a child guidance clinic.

During the past year the school psychiatrist has been placed on a half-time basis and maintains regular hours for conference and consultation with visiting teachers and for the study of problem cases.

Although we clearly see our need for high grade child guidance facilities, our future development will depend upon finances and personnel available. As I suggested earlier, there is much uncertainty in the minds of many of us in regard to the most wholesome development in this whole field. It is entirely possible that, because of the extent of the field and the relatively great expense involved in what we now consider an ideal program, an entirely new approach may be sought.

The development of a mental hygiene viewpoint on the part of the medical and nursing professions will surely permit a much more co-ordinated program than is now possible. I believe that both medical and nursing educators are awakening to their responsibilities in this direction.

Although I have necessarily omitted many details, I hope that I have given you some idea as to what has seemed to us the soundest type of development of a mental hygiene program under the conditions existing in Syracuse.

#### RECOMMENDATIONS

On the basis of this experience, I would be inclined to leave with you the following suggestions:

The development of a mental hygiene program should be placed in the hands of an agency which assumes community leadership and has very definite community force.

This agency may operate within its own field or by coöperation within the field of some other agency either official or unofficial. It can best operate in that field which has great need for development and at the same time offers a setting which promises most easily demonstrable results.

The scope of the work undertaken must be sufficiently limited to guarantee that it will be well done.

No demonstration work should be undertaken except by adequately trained workers. However, this does not mean that all of the adequately trained personnel required for a complete program must be available from the start. A real demand for these may be developed only as the program progresses.

Have frequent reports made by the workers to the agency members. In this way you will develop an interested forceful nucleus.

Carry on a steady educational program as the various groups in the community are ready for it.

Gradually extend the scope of the work, being sure not to lower standards by too rapid expansion or bringing in or tolerating incompetent workers.

Make every effort to carry along the other agencies in the development.

I believe that much of the preliminary program can be carried on even in the absence of an adequately trained psychiatrist. The development of the program will usually create a demand for such an individual.

Just as the development of our child health program created a demand for an increased number of pediatricians throughout the country, so the development of our mental hygiene program will create a like demand for adequately trained personnel. Once established, this demand will just as surely be met.

## Marketing Mass Education\*

HOMER N. CALVER, F. A. P. H. A., AND BERTRAND BROWN

*Assistant Professor of Hygiene, Bellevue and University Medical College, New York University; and Director of the Division of Publication of the Milbank Memorial Fund, New York, N. Y.*

MANY discussions pertaining to health education lead early in their course to confusion of thought because the phase of the subject discussed is not made clear at the outset. To avoid this difficulty the Public Health Education Section of the American Public Health Association several years ago, proposed a terminology for common use. Phraseology was then recommended to define three types of public health educational activity:

1. The formal academic instruction given to students of health was designated as "public health training." (Two different types of training are actually embraced under the terminology "public health training." On the one hand it includes the curricular courses designed for those who are studying to equip themselves as public health workers of one type or another, i.e., public health nurses, engineers, epi-

---

\* Read before the Public Health Education Section of the American Public Health Association at the Sixtieth Annual Meeting at Montreal, Canada, September 16, 1931.

demiologists, etc.; and on the other hand, it includes the incidental training in hygiene or public health given to those who may later become auxiliary aids in the public health campaign, for example, teachers, social workers, and physicians.)

2. The training of children in the school and elsewhere in health habits and the principles of hygiene and public health was designated as "child health education," and this term has become well established.

3. The less formal activities directed to the education of the adult population were designated "popular health instruction," phraseology which has not been widely accepted. The implication here that you cannot educate the mass but only instruct it suggests defeat at the outset.

The subject of this paper cuts somewhat across all three of these distinctive lines of endeavor. In the main, however, it concerns adult health education and child health education outside the classroom. Because neither of the fields indicated, singly or together, serve to emphasize the extent of the problem here in mind (its scope and the methods it necessitates being far beyond those commonly visualized) we have borrowed from contemporary popular educators in China the term "mass education."

By "mass education in health," is meant the dissemination among the whole population of knowledge gained by the technical worker in the field and laboratory to the end that this knowledge may be applied individually and collectively for the prevention of disease, the postponement of death, and the building up of a vigorously healthy population.

Failure to discriminate between the terms "hygiene" and "public health" also results in confusion at times. The one concerns the indi-

*Coney Island crowds are eager for health information and not discriminating as to its source.*

vidual and his personal acts. The other concerns the individual only as a unit of society and his part in the collective acts of the group. Mass health education is concerned with both hygiene and public health and needs to distinguish between them in formulating its programs.

It is not necessary perhaps here to dwell on the importance of public health education. But there have been times in these counsels when the importance of adult education has been allowed to become obscured by emphasis on child health education. Adult education has been considered, when at all, chiefly as instruction in personal hygiene temporarily necessary to correct earlier deficiencies in child health education. Some would have us believe that if we could only thoroughly train one generation of children the necessity for adult health education would thereupon cease. The child is father to the man but the man is also father to the child. And this relationship has significant implications for health educators. In a diphtheria immunization campaign or in such instances as the recent epidemic of infantile paralysis, prevention depends on adult understanding. In many instances, adult education provides society with its only opportunity for reaching the child.

Our whole program of child education is dependent upon a certain amount of adult education, at the very least an amount sufficient to approve appropriations for teachers' salaries. Much educational effort with children is nullified by adult example. Indeed it is often nullified by the example of the teacher herself. It is doubtful if such nullification would be eliminated by offering adequate health education in their youth to future adults, parents and teachers.

How much of the content of one's early training is really carried into adult life? If the principles of health taught in childhood are to maintain their brilliant reality through all the amazing experiences and expanded horizons of adult life, the education of the individual must be everlastingly kept at, through grade school, high school, college, and mature adult life. What Bruce Barton says of advertising is equally true here: "You can't advertise today and quit tomorrow. You are not talking to a mass meeting—you're talking to a parade."

Even though we accept the importance of continuous mass education we have but rude implements with which to perform our tasks. We pour our time and money into posters, pamphlets, lectures, motion pictures and the radio, but we do not know very much about the relative educational value of these technics. Who can say in what circumstance a radio talk is more effective and economical than a motion pic-

*Spacious corridors, colorful designs and artistic presentation of information on hygiene attract many visitors*

*The traveling health museum is independent and self-contained. It carries an exhibition tent on its roof and facilities for displaying a complete hygiene exhibit including motion pictures.*

*Carefully planned dynamic exhibits invite study and compel attention.*

*Permanent displays of three dimensional models at the German Hygiene Museum provide an open textbook on hygiene.*

ture or when a poster will get better results than a pamphlet? Our measurement of the effectiveness of printed matter has too often been in terms of good printing, not in terms of life saving. This is as if the serologist strove for a serum which was crystal clear rather than for one which produced immunity. We cannot assume that because good printing pleases us it will please the public, or that if pleasing it will result in action. It may be that poor printing would save more lives than good printing.

Who can prove that his established use of any cherished medium has value in terms of life saving? What have we to show that the general health of a group exposed to prolonged health educational ministrations is any better off therefor? In our scant attempts to prove the value of our technics, we have been content with subjective standards.

Largely because they have proceeded empirically, health educators are tolerated as step children in the family of public health scientists. The laboratory man and the health officer have shown that toxin-anti-toxin prevents diphtheria. The engineer has reliable statistical evidence that protection of a water supply decreases the incidence of typhoid fever. The public health nurse, the statistician, and the epidemiologist can produce convincing proof of the life saving value of their efforts. If mass education in health is to assume its legitimate place as a valuable routine in the public health campaign, equal in rank to vital statistics, bacteriology, or administration, the value of its methods must be proved, and newer and more effective methods found. It may be no more difficult to establish scientifically the value of our educational technics than it was to establish the value of present-day routines of communicable disease control. Those routines now appear to have been so easily proved, only because they have *been* proved.

The stern discipline of the laboratory and the brilliance of its results have attracted millions of dollars for research. As a result we have, compared with the past, a tremendous store of knowledge in preventive medicine. This is a store in the warehouse sense in that for the most part this knowledge is stored away in textbooks and journals, hidden from the layman among incomprehensible words and symbols and disguised with appalling statistics. Yet the research worker has performed his task. He has found the knowledge he sought. We have failed to make this knowledge available for the service of mankind. Production of knowledge has far outstripped consumption.

It is frequently argued that mass education in health cannot be

effected because the public is not interested in health. This argument is fallacious. It is an alibi undoubtedly often used when salesmen first tried to introduce the "horseless carriage." But the science of public health is not in the "horseless carriage" stage. There is abundant evidence of a ready market for health. Last March we visited the boardwalk at Coney Island. In spite of bristling weather, we found crowds gathered to listen to so-called health lectures by modern medicine men. These spell-binders are known as pitchmen. They sell books, rubber exercisers, psylla seeds, ointments, tonics and whatnot. They appreciate the dollar and cents value of the health appeal and the visual method. They constitute a clearly defined group on the edge of the entertainment profession. The health appeal has been seized upon also by producers and distributors of all types of articles in selling their wares. Automobiles, soap, refrigerators, underwear, toys, books and, of course, all sorts of foods are urged upon us for their health value. That the health motif has such universal commercial importance would indicate sufficient popular interest to insure success in any mass movement in health education, if the proper technics were used.

Hope for the future lies in our emergence from the empirical stage. With the help of our scientific confreres, we must test by objective standards our long established practices. But while undergoing such self-analysis, and perchance resultant housecleaning, we cannot profitably sit idly watching the parade go by. The problem of mass health education here outlined calls for the inauguration of methods adequate to the new concept which has already been caught by commercial interests.

That mass education, conceived in the broadest possible terms, is necessary to secure the utilization by individuals and communities of available demonstrated health knowledge, which, applied, would lengthen life and make it happier, this group does not need to be persuaded. Any methods, new or old, which will help to raise the health intelligence of the masses, this group will welcome. Proponents of visual methods of health instruction believe that wider use in America of the museum method, its value in other fields long since well established, will be a means of reaching thousands of individuals who are now indifferent to other appeals.

The museum of hygiene has demonstrated its success in Germany and elsewhere. As a museum it is not merely a repository of historical objects and data but a true educational institution. It is fundamentally a permanent exhibition of devices cleverly arranged to command interest and crystallize understanding. Such an institution

would draw its elements from many sources. It would be equipped with workshops, research laboratories, lecture rooms, a library, broadcasting studio and auditorium, in addition to spacious exhibition halls. It would serve as a center for research, experimentation and demonstration in visual and other unexplored methods for disseminating health knowledge.

There is probably no better existing model for such an institution than the Deutsches Hygiene Museum in Dresden. A museum like that in Dresden, adapted to American needs and medical standards, would be an important adjunct in spreading health knowledge among the masses, as well as in offering health education in elementary and secondary schools. It would also be a valuable aid in teaching hygiene in schools of medicine. For industry, as well, such visual instruction as only a museum could provide would be of inestimable benefit in instructing workers in accident prevention and health preservation.

A suitable building for such a museum would have ample proportions, easy accessibility, and possibilities for future enlargement. Among the exhibits would be wax, glass, and plaster models, charts, and posters. They would visualize all health problems related to the more common diseases in a manner so graphic and dramatic as to command the attention of the average layman and be readily understood by him. They would provide instruction on the structure and functions of the various parts of the body. They would illustrate such subjects as biology, personal hygiene, mental hygiene, care of the teeth, nutrition, prenatal, postnatal, and child care, communicable disease control, tuberculosis, venereal diseases, tropical diseases, hygiene of work and the protection of the worker.

The Deutsches Hygiene Museum began its existence in 1911 in connection with the first International Hygiene Exhibition. In 1930, the opening of a new and spacious permanent building for the Museum served as an occasion for holding in Dresden the second International Hygiene Exhibition, an event which was repeated in the summer of 1931. The permanent exhibits which this new building houses are the last word in visual health instruction. The charts, specimens, models and apparatus used are striking in design and compelling in interest.

A unique feature of many of the displays is their movability, that is, many models are so arranged that the museum visitor may operate them by turning a crank, pushing a lever or touching a button. This not only excites curiosity but compels attention and probably assures that the lesson of these particular displays at least will be remembered.

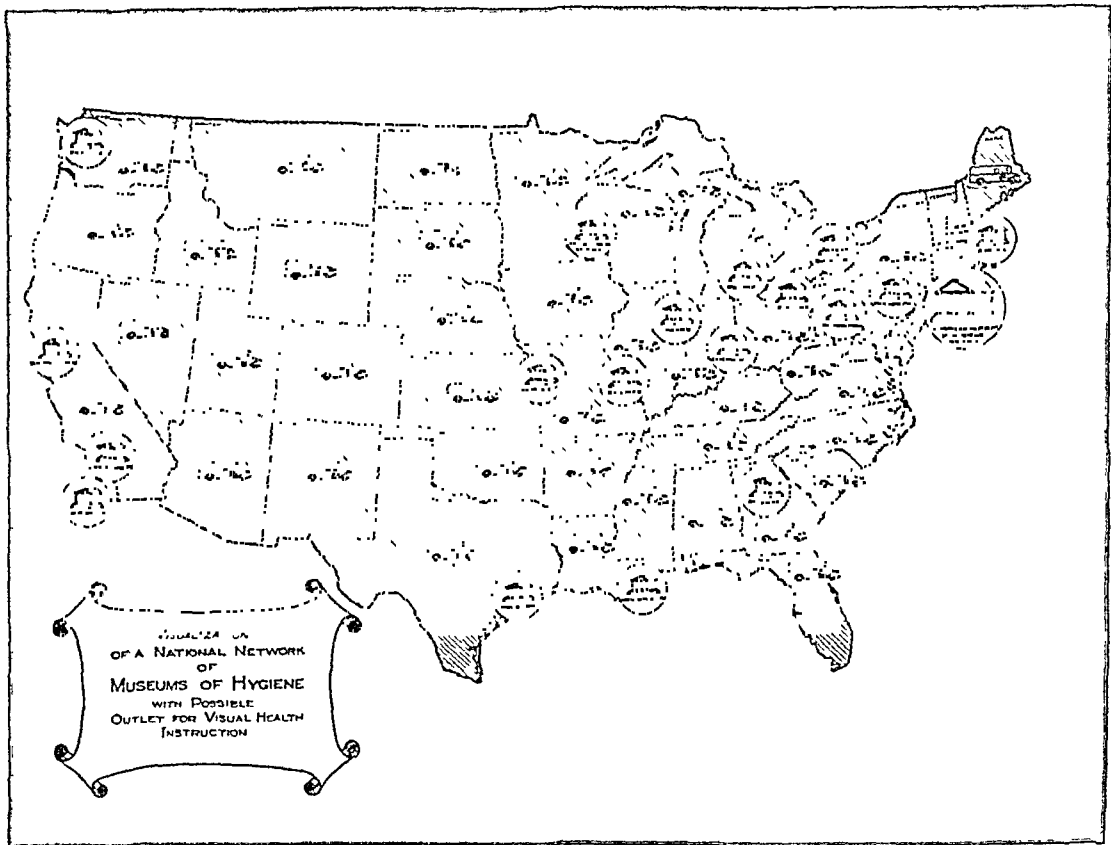

These devices are most valuable also in attracting visitors to the museum.

A determined and highly successful effort has been made to keep all descriptive texts in the simplest language. The deadly seriousness which so often marks the effort to portray scientific information is absent to a large extent. Indeed many of the charts and legends are quite droll, and this effect has been achieved without sacrifice of professional standards.

The German museum probably goes further than public health workers in America would find it judicious to go in its emphasis on physiology and personal hygiene at the expense of community hygiene. It has, however, successfully maintained a balance between the various special hygies. Such an exhibit gives to the man in the street a means of separating the true from the false and differentiating between the important and the trivial in the health propaganda to which he is subjected today from a variety of special interests.

Such a museum established in a large city in America might well become the headquarters for an extensive educational program comprising both intramural and extramural activities. Among the intra-

*The concept of a national network of museums serving to disseminate health knowledge among the masses is inspiring to contemplate.*

mural activities there would be lectures based on exhibits; radio broadcasts as dramatic in their way as the exhibits themselves; specially prepared exhibits on subjects of timely interest, such as influenza and infantile paralysis; and regular courses in hygiene and health education in coöperation with local schools and universities.

If the full value of the museum were to be realized, however, its activities could not be confined to its own building, or its home community. It would, for example, develop small portable loan exhibits for which there is an ever-present demand. Official and voluntary public health agencies have now neither the funds nor adequate experience in exhibit technic to provide sufficient valuable material of this type. Traveling exhibits such as the motorized exhibits of the German museum might well be utilized. In coöperation with state health departments, a number of which are already utilizing traveling exhibits, this would provide an admirable method of reaching rural populations. In time these temporary exhibitions might stimulate the development of a number of permanent museums, locally financed.

The question of financing such developments is one that we do not propose to raise here. Support has been forthcoming in the past for worthwhile projects. And if professional health educators in America earnestly desire such institutes for health education, and adequately voice that desire, undoubtedly support for them may be had in the not too distant future.

If we are to reach the masses, we must enlarge our view of the size of the job that confronts us. We cannot leave off with any temporary popularization of a few simple ideas. The task must be institutionalized. All phases of the health education movement must be utilized in concerted effort. New and effectual methods must be devised and continuously utilized in educating the whole mass of the population, generation upon generation, as to the importance of achieving, and the methods for achieving that summit of racial well-being which the searches of pioneers have made distantly visible. It is believed that museums of hygiene would serve as permanent centers for research and experimentation in health educational method and as a continual inspiration to reference sources for health educators. The concept of a national network of such institutions, serving in concert as a far flung, permanent and living force for the dissemination of health knowledge among the masses, is noble in purpose and inspiring to contemplate.

## Medium City

W. W. BAUER, M. D., F. A. P. H. A.

*Commissioner of Health, Racine, Wis.*

THE health of the child has been recognized as the most favorable point of attack in initiating a community health program. Scientifically, this choice is sound because we all recognize that not much is to be expected of efforts directed toward the health of generations which have reached adult life, while, on the other hand, the child is plastic. Moreover, if we are successful with the child of today, we have accomplished something for the adult of tomorrow and may reasonably expect that when our failing hands relinquish their activity we may find others who can carry on as well as we have—or better.

In attacking the question of child health in a medium sized city, we must first consider what the needs of the community are. What is its infant mortality? What are the component elements of the infant mortality—are the infant deaths occurring in the first few days of life, in the first month, or during the last 11 months of the first year? What are the leading causes of infant deaths? prematurity, diarrheal diseases, or respiratory diseases? What is already being done in the community with respect to the health of its children? Is there a safe water supply? Is pasteurized milk from tuberculin tested cattle available? Is the board or department of health functioning in child health work? If not, have there arisen voluntary groups to meet the need? If there are already workers in the field are they working toward the proper objectives as shown by the needs, or are they merely going through a routine copied from other communities? These, it seems to me, are questions which must be answered satisfactorily before we can proceed to discuss what the child health service of a given organization shall be.

It has always been fairly easy to establish child health programs in a community because of the sympathy for children, and especially for

---

<sup>\*</sup> Read at a Round Table of the Child Hygiene Section of the American Public Health Association at the Sixtieth Annual Meeting at Montreal, Canada, September 15, 1931.

babies, which is so easily aroused by appeals to the emotions. Unfortunately, while the response is usually generous it is not always wise. Too often it takes a form which at the outset seriously handicaps future progress of the work. Altogether too frequently child health programs, initiated either by voluntary or official organizations, fail to take the medical profession into their confidence and thus antagonize the physicians in the beginning. It is a much more difficult and time consuming task to overcome an established antipathy than it would have been to proceed from the beginning without creating needless antagonism.

The first question that is put before us is whether the public health aims and services of infancy, preschool and school health programs should provide medical and nursing service for sick children or for well children only. I wish to answer that question categorically in the negative as far as sick children are concerned. In my judgment, the community has a very definite responsibility for the dissemination of health information, and I believe that the demonstration method is the only one which will ever produce worthwhile results.

For well children there should be free facilities provided by the community, which should by actual demonstration teach the mother the proper care and handling of a new baby. This means clinics for physical examinations plus nursing service with demonstrations of bathing, formula preparation, clothing the baby, and advice as to exercise, sleep, sunshine, fresh air and routine of life. Such a service should be free to all, regardless of their economic status, because we know that it is not alone the poor and the unfortunate who are lacking in health information concerning their children.

On the other hand, the sick child is placed by the very fact of its illness outside the pale of preventive medicine. I recognize that there are border-line cases in which doubt may well arise as to classification, but most of these belong in the hands of the family physician or of the medical service provided by the community for the indigent sick. In my judgment, this latter should be definitely differentiated from the preventive service offered by the community.

I am definitely opposed to state medicine. I believe, and I think an overwhelming majority of the medical profession of this country believe with me, that the relationship between the doctor and the patient is a delicate, highly personal one which cannot and ought never to be standardized. When the community steps between the patient and the doctor, and the doctor becomes a paid servant of the state, both patient and doctor lose that indefinable relationship which has set the practice of medicine on a plane apart from all the other learned

professions. Therefore, for the community to provide medical service for the sick, unless they be indigent, is certain to lower the quality of medical service which the patients will receive.

We have but to look about us to see how difficult it is to get the more able and successful of our citizens to enter public life. They know from observation that a public servant is the target for unjust, frequently unreasonable, sometimes libelous, and almost always destructive, criticism. It is only the man with an extraordinarily placid disposition, or whose enthusiasm for the cause enables him to brush aside the irritations of public life, who can long survive in public office. If this is true of non-professional men, how much more forcefully does it apply to the doctor!

The doctor has always been an individualist, and I hope and trust that he will always remain so, though perhaps with a somewhat improved capacity for coöperation. The greatest leaders and teachers in medicine have repeatedly admonished their students that it is the patient who must be treated and not the case. If the community provides medical service for the sick, it must do so upon a mass basis; otherwise the cost becomes prohibitive. Preventive measures may be applied collectively, but sick people cannot be treated *en masse*; they demand, and are entitled to receive individual consideration.

Therefore for the infant, the preschool child, and the school child—and may I add the expectant mother—we may and should, through the community, provide health information and preventive service, but we must not mix our preventive program with community relief lest we unwittingly destroy both. Public health nursing has long held this as a basic tenet in its code of ethics.

The second question placed before us is whether the service for well children should be limited to education of parents, or is it the responsibility of the community to provide advisory medical service to safeguard the health of the children? It seems to me that our objective should be the education of parents and that our service should be limited to that objective. By education of parents I do not mean that we shall confine ourselves to the everyday educational weapons now commonly employed by health departments, such as pamphlets, indoor and outdoor posters, radio talks, group addresses, classes for mothers and little mothers, and exhibits. These means should be employed but there should also be education by demonstration. That means clinics at which well babies should be examined and at which the mothers can have demonstrated to them the condition and health of their babies; and that preschool children and school children should have physical examinations provided by the community.

I think, on the other hand, we have too often followed the line of least resistance. I recall very well the establishment of a child health center in a certain community. It was established by a voluntary agency, though the same error which I am about to elucidate might just as well have been committed by an official agency. In short, there was a section of this city populated largely by people of good education and economic status somewhat above the average. Many of them were college graduates; all had at least a high school education; and all were intelligent and progressive. They organized, and requested the establishment of a child health center in their neighborhood.

When the health officer was consulted, he pointed out to the committee that with funds available for only one more center, it was better to open it in a locality where the need was greatest. He was met with the argument that in the location he suggested there was no demand for the service. He attempted to point out that the very existence of a demand where they proposed to establish the station was evidence that the need for education in child health was less in that locality than in the other where no demand existed.

He made a spot map for them of infant deaths over a 5-year period and showed them that it was decidedly clean where they proposed to establish health service for babies and very markedly spotted in the other locality. He was overruled and has since on a number of occasions been shown the remarkable records of attendance at the baby clinic which was established in response to this vocal demand.

This instance seems to furnish the answer to a number of questions which I asked in opening this paper. Obviously much more good could have been done by opening a baby clinic in the center of a locality populated largely by laboring people of foreign descent and tackling the hard and much less attractive problem of awakening these people to a need which they did not even suspect.

I am a firm believer in the clinic method of objective demonstrations, and I think it should be open to all to teach the mothers what they ought to know about the health of their children. Nevertheless a mother who has 6 or 7 babies perhaps in as many years should not be encouraged to bring them, one after another, to a child health clinic, unless she is of low mentality, and is unable to learn from experience. I think that when her first baby has had the advantages of advisory service, she should not be allowed to shift her responsibility to the community as subsequent babies arrive, except perhaps to bring a new baby once or twice to refresh her mind. Should there not be graduation from health education as well as from other kinds? Should the

mother not be expected to learn, after a reasonable time, to go to her family doctor for well baby supervision? I am assuming that the family is able to pay for supervisory health service. If unable to pay, then of course the community owes it to her and to her baby to give her service indefinitely.

Let me not be misunderstood when I refer to the launching of public health projects without the coöperation of the medical profession. I am not making any plea for toleration of reactionary physicians who obstruct all progress and who oppose public health projects because of the mistaken idea that the economic effect upon the medical profession will be bad. We know that in the larger view, educational activities in the public health field, even when they render a considerable measure of advisory service, react to the benefit of the physicians. I believe that the more farsighted of the medical profession fully agree in this opinion. What I do want to emphasize is that public health is and must be based on the medical sciences. It is true that public health objectives are strongly tinged with social and economic aspects, but basically they are medical. It seems but logical that the medical profession should have a large measure of consideration in their inception and development, not for the sake of the medical profession, but for the benefit of the public health.

I am perfectly aware that organized medicine has not always assumed the leadership in the field of public health which might logically be expected of it, though it was doctors who first demanded health departments in many communities. It is, no doubt, partly the fault of the medical profession that the situation exists as it does, and yet we in the public health field are by no means blameless. Too often we evolve a full blown and—to us, at least—very beautiful project and seek the endorsement of the medical profession without ever having consulted them during the process of development and preliminary discussion. Being but human, they are resentful and we sacrifice coöperation which ought to be ours, and without which we can ill afford to proceed.

When the medical profession has been given due opportunity to participate and coöperate in public health work and has declined, rejected, or attempted so to hamper the work with restrictions that it becomes meaningless and futile, then obviously there is nothing to do but proceed to meet the community need, regretting the lack of participation by organized medicine.

Finally, in supporting my opinion that public health work should be limited to education and demonstration and should not attempt to supplant the family physician, I wish to cite the growing tendency in

this country toward paternalism in government. This tendency has been attacked often enough of late, and yet it proceeds apace. There is a growing feeling on the part of our citizens that they can and should thrust all their responsibility upon their government. A man buys a dog for a pet; the dog becomes mad; his owner calls upon the city to come and get the dog and either care for him or destroy him. Why should the community relieve him of a responsibility which he created? A small child playing alone on the street is the victim of an accident and the neighbors and friends proceed to condemn the community government because there was not a policeman on that spot at that moment to prevent the tragedy. Where were the parents? and why was not this child better guarded by them? An economic depression unbalances the wheels of industrial progress and a clamor arises for government to wave a magic wand and right matters overnight. Cannot business and industry stand on their own feet? Such examples could be multiplied without end.

Our nation was built upon individual initiative; today there is grave danger that in taking away from the individual too much of his responsibility we are going to destroy his resourcefulness, his self-reliance and his independence.

For those reasons which I have here imperfectly outlined to you, I believe that public health projects in the infant, preschool and school fields—and in others not here under discussion—should have education for their objective more and more, and service less and less.

---

### Premiums to Mothers, Liège, Belgium

TO overcome the indifference of women to prenatal work and to infant health work, the municipal council of Liège, on July 1, 1931, offered premiums of 200 francs each to expectant mothers who attended regularly a prenatal health center or were examined by their own physician at least once before the end of the 6th month of pregnancy and not less than 3 times during the entire pregnancy, and who have had their infants regularly examined either at a health center or by the family physician. The premium is paid 3 months after the birth of the child.—*Oeuvre Nationale de l'Enfance, Revue Mensuelle*, Brussels, July, 1931, p. 776.

## Public Health Service Hospitals Now Maintained at 155 Ports

**A**PPROXIMATELY 500,000 persons apply yearly for care, treatment and physical examination at hospitals and other relief stations which the U. S. Public Health Service maintains at 155 ports of this country and its possessions.

Practically every class of disease is found among these patients. In the care and treatment of them, valuable scientific knowledge constantly is gained.

In the 25 marine hospitals operated by the Service more than 300 doctors and dentists, over 400 nurses, aides, and dietitians, and approximately 1,800 other persons are constantly employed in the care of a daily average of about 4,000 patients. The annual expenditures in the marine hospitals and other relief stations are more than \$5,000,000. The marine hospitals are all general medical and surgical hospitals except the hospital at Carville, La. (National Home for Lepers), which is devoted to lepers, and the hospital at Fort Stanton, N. Mex., to which are transferred merchant seamen and other beneficiaries with tuberculosis, suitable for treatment in a high altitude.

The Marine Hospital at Ellis Island, while primarily designed for detained immigrants, is also used for regular service beneficiaries, and all the marine hospitals admit patients of the Veterans' Bureau when facilities permit. New marine hospitals have recently been completed at Detroit and Cleveland, others are in process of construction at San Francisco (500 beds), Galveston, and New Orleans (600 beds), and new marine hospitals have been authorized in New York (600 beds), Baltimore, and Seattle. The building program is necessary to keep pace with the development of the American merchant marine and to fulfil other obligations of the government to provide hospital treatment.

Those who now are entitled to the medical care and treatment from the Service are as follows:

1. American seamen employed on board in the care, preservation, or navigation of any registered, enrolled, or licensed vessel of the United States.
2. Officers and enlisted men of the Coast Guard.
3. Officers and seamen on vessels of the Coast and Geodetic Survey.
4. Officers and crews of vessels and certain keepers and assistant keepers of the Lighthouse Service.
5. Officers and crews of vessels of the Bureau of Fisheries.
6. Immigrants detained at immigration stations.
7. Seamen from vessels of the Army Engineer Corps and other vessels belonging to the United States Army.
8. Seamen employed on vessels of the Mississippi River Commission.
9. Beneficiaries of the United States Employees' Compensation Commission.
10. Patients of the Veterans' Bureau.
11. Lepers.
12. Officers of the Public Health Service and employes on field duty.
13. Prisoners at United States penal and correctional institutions.
14. Patients at Federal Narcotic Farms.

## REGISTRATION FEES AT ANNUAL MEETINGS

FOR the first time in the history of the American Public Health Association, the registration fee plan was established at the Sixtieth Annual Meeting in Montreal. Previously, it had been the custom to levy a tax of \$1.00 upon non-members of the Association registering at the annual meeting. This year, members and non-members alike were asked to pay a fee of \$2.00 when they registered. This innovation caused some discussion and a few protests. The Committee on Meetings and Publications, upon whose recommendation the plan was approved by the Executive Board, has been requested to explain to the membership why the recommendation was made and why the practice will be continued at the Washington meeting in 1932.

Like many organizations, the American Public Health Association has had difficulty in financing its annual conventions. Until the Committee on Meetings and Publications assumed the responsibility for the conduct and management of meetings, the annual meeting was expected to be a source of revenue for the Association. Not only was the city entertaining the Association called upon to provide entertainment for the visiting delegates, but it was also expected to raise sufficient funds to turn in to the Association treasury a considerable balance after all local expenses had been met. The success of an Annual Meeting came to be measured largely by its financial return, and the

meeting went to the highest bidder. This system placed an undue burden upon the health workers in the convention city. Money-raising became a bug-bear, and many communities that desired the meeting naturally showed hesitation in issuing invitations because of the financial responsibility involved.

The committee faced this situation frankly and determined to change it. It was decided that in future no financial guarantee from any city will be required. The expenses of the executive office will be financed as far as possible from the sale of exhibit space. The local committee in the convention city will be asked to provide entertainment only, and that entertainment may be as simple or as elaborate as the local committee determines.

The term "entertainment," as used here, must not be interpreted as meaning social and good-time functions exclusively. Included in "local entertainment" are those things that can be supplied without considerable expense by any community with an organized convention bureau. We refer to registration and information personnel, registration equipment, stenographic service, etc. Included also is transportation of delegates by the most convenient and economical means to places of public health significance in and around the convention city. The providing of music for dancing, the printing of a directory of points of scientific interest, and other small practical items that contribute to the success of a convention are included further under the general heading "entertainment."

Since the financial responsibilities of a city entertaining the American Public Health Association have been so materially lessened, the number of annual invitations has greatly increased. No community finds the demands unreasonable. The expenses of the executive office are still to be met, however. Program building, which requires the calling together of some 25 section and committee representatives two or more times a year, is expensive. Program printing is expensive. The membership must be kept informed of annual meeting plans by mail. A publicity appropriation is an essential. An annual meeting city cannot be selected solely because a large amount of exhibit space can be sold there. Occasionally a city is chosen that makes little or no appeal to the commercial exhibitor. Then the income from the sale of exhibit space drops, but the expense of the meeting remains fairly stationary.

It is to provide a margin of safety for the executive office that the registration fee plan has been adopted. It should be borne clearly in mind that no salaries and no overhead are included when annual meeting expenses incurred by the executive office are calculated. Only

those expenses are considered that would not be incurred if no annual meeting were held.

The protest has been recorded that the registration fee penalizes the member who attends the annual sessions. It is true that he makes a nominal contribution to its costs, which the member staying at home should not be expected to pay. However, he is provided, through co-operative action, with much more than he could possibly buy by spending the same amount himself. The Committee on Meetings and Publications believes or estimates that the average delegate spends between \$100 and \$200 in attending a convention; hence an additional \$2.00 paid as a registration fee is not a great factor in his expenses, while the total of registration fees may make the difference between a balanced income and expense statement on behalf of the annual meeting and a considerable deficit.

The committee further justifies its recommendation for the registration fee plan by calling attention to the fact that more than 50 per cent of the organizations of the country have adopted it, according to the International Association of Convention Bureaus, and "in virtually no case has the plan ever been abandoned once it was adopted." The range of fees charged is considerable, \$2.00 being the minimum, and running up to \$10.00 for some groups.

The Committee on Meetings and Publications feels that \$2.00 for everyone attending the meeting is a fair charge. Under existing circumstances it would not recommend a larger fee, and it anticipates the day when annual meetings can be adequately financed through other methods. In the meantime, it considers prevailing practice a safe guide.

### THE ANTI-INFECTIVE ACTION OF VITAMIN A

MUCH has been written concerning the vitamins, their necessity in nutrition, and in fitting the body to resist infection. In 1929, Edward Mellanby and his coworkers reported favorable results in the treatment of puerperal septicemia with preparations containing vitamin A, which led them to the conclusion that the demonstration of curative effects argued that this vitamin would have a much greater prophylactic power. Experiments on young animals with vitamin A and with carotene led them to believe that these agents were "anti-infective" in their action. They have since carried out an extensive series of experiments on pregnant women. During pregnancy the mother not only has to keep her own body well nourished, but must supply all substances necessary for the development of the fetus; she

must store vitamin A in her liver, as well as supply it or its precursor, probably carotene, to the liver of the fetus. An examination of fetal livers by one of the authors has shown that the majority of them contain vitamin A in varying quantities.

For the experiment 550 women attending the outpatient department of the antenatal clinics of Sheffield were selected, all of whom were subsequently delivered in a hospital. Those who did not enter a hospital for delivery were not included in the results. Radiostoleum, a preparation containing the sources of vitamins A and D dissolved in a neutral oil, was given to the women, preferably a month before delivery, though in some cases for 2 weeks only. Without selection, alternate women were given a supply of this material with instructions for its use. There were 275 women who received the vitamin preparation, while 275 acted as controls. The number of primiparae and also those who required manual or instrumental intervention was almost equal. Other complicating factors were almost equally distributed in the 2 groups. In the group taking the radiostoleum, judged by the B. M. A. standard, there was an incidence of morbidity of only 3 cases, or 1.09 per cent, while in the control group there were 13 cases, or 4.73 per cent. At the Jessop Hospital, the morbidity rate was 5.8 per cent as compared with the average rate of 3 years for that hospital—6.8 per cent. The group receiving vitamin had a morbidity rate of 1 per cent, while the control group had 5.8 per cent. Another point of interest brought out was the fact that the total number of pyrexial cases among the women taking vitamin was 56, or 20.4 per cent, while in the control group it was 98, or 35.6 per cent, a difference of 15.2 per cent, which the authors point out is practically 4 times the standard error, and therefore significant. Among the vitamin group, only 4 women had pyrexia which lasted from 1 to 3 weeks, while there were 10 of this character in the control.

The authors believe that these results are significant, showing an increased resistance to infection on the part of the treated women, with a decrease in the clinical severity and duration of the infection when it did occur. They also concluded, on experimental evidence, that vitamin D had little to do with the results, though they do not entirely exclude it as a factor, since the normal calcium metabolism requires some source of vitamin D.

The authors of this paper are well known as careful students and experimenters. If their results are confirmed they will prove a boon in childbirth. America stands low in the list of nations in regard to maternal mortality, and any preventive measures which offer such help would seem to deserve careful investigation.

The so-called anti-infective power of vitamin A has received a good deal of attention for some years past. It has been used in hearings on filled milk before committees of Congress, the argument being that cream and butter fat aided in the prevention of tuberculosis.

Professor Mellanby and his wife, who is well known for her work on the relation of vitamins to the development of teeth, have for some 5 years taken cod liver oil daily, and during that time have been practically free from ordinary colds, which they attribute to the vitamin A. Needless to say, this is not a controlled experiment, though interesting, especially when taken in connection with the observations on puerperal women.

## LETTERS FROM GREAT BRITAIN

AT the suggestion of Dr. Charles Porter, the Editor of *Public Health*, the official organ of the Society of Medical Officers of Health, an exchange of letters has been agreed upon between him and the Editor of this JOURNAL, who will be assisted by the Associate Editors of the JOURNAL in the collection of matters of interest. We are sure that Dr. Porter's letters will be of general interest to our readers, and we hope that the American letters will also appeal to the readers of *Public Health*. On our part, it can only be said that we look to England as the place of origin of modern public health. The work of Chadwick began the movement in that country, which soon spread to the United States through the foresight of

Shattuck. England now has a Minister of Health in the Cabinet, with Sir George Newman as the Chief Medical Officer. The Medical Research Council of England has for a number of years put out much of the very best public health literature, based on careful studies, that we have.

As Editor of *Public Health*, Dr. Porter has direct access to the best sources of information in England. Personally, no man in that country is better fitted to select and write of health matters than he. His large experience in medical matters coupled with his legal knowledge, for he is a barrister at law as well as a physician, enables him to discuss health work from every angle.

### FROM A CORRESPONDENT IN GREAT BRITAIN

#### THE NEW "NATIONAL" MINISTER OF HEALTH

The tumult and the shouting of what, in the journalistic phrase, is the most remarkable election of modern times having died, there remains to be seen what is to be the effect on health works in Great Britain of the various economies announced as necessary. In this connection, it may be noted that more or less of a promise was given that the activities to be least and last interfered with would be those affecting the public health. In any case, it is unlikely that anything dramatic or drastic will be attempted at first or even eventually. In selecting the Minister of Health in his administration, Mr. MacDonald, it is suggested in some quarters, was thinking more of his Cabinet than of the Department; Sir Edward Hilton Young being of the type and possessing the ability required at

the present juncture, and being comparatively unheard of in relation to public health matters. As a matter of fact, statements of this kind are not uncommonly made apropos health ministers in England. The fact that the individuals appointed rarely hold the position for long, but pass on to what are regarded as higher cabinet posts, supports the view, frequently expressed, that it is something of a stepping-stone, and that particular knowledge of, or a special flair for, the work is unnecessary since the permanent officials are capable of doing all that is required. That there is a good deal of exaggeration in these statements in the case of Sir Edward Hilton Young may be taken, since, having occupied the position of Crown representative on the General Medical Council, it may be accepted that he has acquired some knowledge of preventive medicine that will prove useful at the

Ministry and beneficial to the public health at large.

#### THE UNEMPLOYED AND WATER WORKS SCHEMES

The possibility that the public health may require benefiting is one not to be overlooked. Considerable optimism exists in some quarters on account of the fact that the numbers of unemployed have fallen. Against this must be set, however, that the unemployment pay (the so-called dole) has been reduced, as have also wages in the bulk of the trades. Nutrition as a result is certain to suffer, and with it the health of the people. The public assistance bodies throughout the country anticipate that heavy claims will be made upon them during the winter. Local authorities also, desirous as they are to economize, are certain to find the provision made for supplying nourishment to expectant and nursing mothers and to babies, on the recommendation of medical officers of welfare centers will be heavily taxed. Among works put in hand with the object of assisting the unemployed it is interesting to note that several schemes for providing or improving water supplies are included. The city of Manchester, for example, has in hand an additional scheme estimated to cost £1,500,000 and the Durham County Water Board is engaged in the provision of a new reservoir costing about £1,000,000. Sanction to borrow up to £3,116,000 for expenditure on similar purposes was granted during the past year by the Ministry of Health. In this connection it is noted in the report of the Ministry that there is an increasing tendency toward more comprehensive schemes instead of a multiplication of small schemes, and that the larger local authorities, seeking new or additional sources, are inclined to arrange matters so that they may supply others who happen to be in the neighborhood of their aqueducts. This is all to the

good, since, though the improvements in the supplies of the smaller areas, rural particularly, are most encouraging, there remains much to be done before conditions in these can be regarded as generally satisfactory. As a result of the operation of the Local Government Act, it is hoped that more active progress in this direction may be made.

#### LOCAL GOVERNMENT ACT AND FULL-TIME HEALTH OFFICERS

This is not the only line that progress may follow in the case of rural districts as a result of the operation of the Act mentioned. One in particular is in respect of the services of a health officer, and in this the Ministry report directs attention to a requirement of the Act that every county council after consultation with district councils shall formulate arrangements, by combination of districts or otherwise, for securing that every medical officer of health subsequently appointed for a district shall be restricted by the terms of his appointment from engaging in private practice as a medical practitioner.

For the guidance of county councils, the Ministry of Health has issued a memorandum setting out a number of methods by which the services may be secured of medical officers of health devoting the whole of their time to public duties, and describing various forms of combined appointments for consideration, e.g., medical officer of health and school medical officer, medical officer of health and tuberculosis officer, etc.

During the year, 42 health officer appointments approved were of the whole-time class, this being about half the total number of approvals granted by the Minister.

In the Society of Medical Officers of Health a considerable number of the members hold part-time appointments only, or are assistant medical officers carrying out specialist duties in relation to schools, tuberculosis, maternity

and child welfare, venereal diseases, etc. At the last meeting of the Society, one of the most important items on the agenda was the election of the President and other officers for the ensuing year. As President, Dr. Killick Millard, Medical Officer of Health of Leicester, was chosen; Dr. George F. Buchan and Dr. Charles Porter—both of whom are Honorary Fellows of the A. P. H. A.—being selected, the former to act as Honorary

Treasurer, and the latter as Honorary Editor of *Public Health*, the official organ of the Society. The President contributed an interesting and thoughtful address on "Voluntary Euthanasia" in which he put in a plea that its practice, with proper safeguards, should be legalized, and submitted draft of a law which he considered would cover the points of importance.

CHARLES PORTER, M.D.

## LETTERS OF APPRECIATION

AT the Montreal meeting six Honorary Fellows were elected from England. These were Sir Arthur News-holme, Sir George Newman, Sir W. Leslie MacKenzie, James Fenton, M.D., Charles Porter, M.D., and Sir Allan Powell. Of these the last three were present at the meeting, and, together with George F. Buchan, M.D., presented a symposium on Public Health Administration in Great Britain.

The following appreciative letters have been received from The Royal Sanitary Institute and The Society of Medical Officers of Health:

Dr. Kendall Emerson, Secretary,  
American Public Health Association,  
New York City.

Dear Dr. Emerson,

The Council of the Society of Medical Officers of Health have directed me to tender you their sincere thanks for your kindness and hospitality to the Society's delegates who recently returned from a memorable journey in the United States and Canada. These gentlemen have reported in the warmest terms on the welcome they received, not only at the Congress of the American Public Health Association which was the main purpose of their visit but at every point of their journey.

This Society was from the first anxious to take the opportunity of sending a delegation to the Montreal Congress, but it is especially gratifying to feel that in these difficult times the links between preventive medicine on opposite shores of the Atlantic have been strengthened and our mutual understanding still further augmented.

With again many thanks for your part in making our representatives welcome,

I am, Sir,

Yours very truly,

(Signed) G. L. C. Elliston

Executive Secretary

The Society of Medical Officers of Health

1, Upper Montague Street,  
Russell Square,  
London, W. C. 1,  
2d November, 1931.

Dr. Kendall Emerson, Executive Secretary,  
American Public Health Association,  
New York, N. Y.

Dear Sir,

The Members of the Royal Sanitary Institute delegation to the United States of America and Canada (Dr. Charles Porter, Dr. George F. Buchan and Dr. James Fenton) have reported to the Council on their visit, and the many interesting things which they saw, and the valuable information they have obtained.

The Council feel that great benefit must accrue from this interchange of thought and ideas between officers engaged in the service of the public health, and they desire me to express to you their sincere thanks for the kindness and hospitality which you so kindly extended to the Members of the Institute's delegation, as a result of which their visit was made so pleasant, as well as instructive.

Yours faithfully,

(Signed) J. W. Dudley Robinson

Secretary

The Royal Sanitary Institute

90, Buckingham Palace Road,  
London, S. W. 1,  
26th October, 1931.

## NEW MEMBERS

*The following list includes applicants who have been approved for membership in the A. P. H. A. by the Sub-committee on Eligibility. These new members have requested affiliation with the sections indicated, and action by the Section Council will follow.*

### *Health Officers Section*

Archie Cole, 318 Rose Bldg., Pampa, Tex.,  
City Health Officer  
Jaynes M. Crumb, M.D., South Otselic, N.  
Y., Health Officer  
Emil O. Ficke, M.D., Dept. of Health, Daven-  
port, Ia., Director of Public Health

### *Laboratory Section*

M. Dorothy Beck, Berkeley, Calif., 1636 Jose-  
phine St., Bacteriologist  
Rhoda W. Benham, Ph.D., 630 W. 168th St.,  
New York, N. Y., Mycologist, Vanderbilt  
Clinic  
K. H. Clough, 2015 Franklin Ave., Houston,  
Tex. (Assoc.)  
Dr. Alfredo Iglesias, Constitucion 13, Vera  
Cruz, Mex., Jefe de la Unidad Sanitaria Co-  
operativa de este Puerto  
Seymour C. Schwartz, M.D., Baltimore, Md.,  
4006 Bateman Ave., Student, formerly with  
U. S. Army Medical Corps

### *Vital Statistics Section*

Abraham S. Pactovis, Health Dept., Quincy,  
Mass., Statistical Clerk

### *Public Health Engineering Section*

Benjamin V. Howe, State Bd. of Health,  
Denver, Colo., State Sanitary Engineer  
James M. Jarrett, LaFayette, Ga., Box 56,  
Sanitary Engineer, State Board of Health  
Ernest H. Salmon, North Battleford, Sask.,  
741 Main St., Supt. of Water Supply

### *Food and Nutrition Section*

Paul J. Zentav, M.D., 322 Beaumont Bldg.,  
St. Louis, Mo., Secretary, St. Louis Pure  
Milk Comm.

### *Child Hygiene Section*

R. Grant Barry, M.D., Wood School, Academy  
St., Trenton, N. J., Medical Director, Tren-  
ton Public Schools  
Carl C. Dauer, M.D., 434 N. High St., Salem,  
Ore., Director, Child Hygiene, Marion  
County Health Dept.

Horace M. Fooder, M.D., 110 Black Horse  
Pike, Williamstown, N. J., Medical In-  
spector, Monroe Township Public Schools  
Frederick K. Lam, M.D., Bureau of Mater-  
nity, Infancy, and Child Hygiene, Board of  
Health, Honolulu, Hawaii, Director  
Russel H. Williams, M.D., Box W, Granville,  
O., University Medical Officer

### *Public Health Education Section*

Carl L. Anderson, Ann Arbor, Mich., 108 W.  
Williams, Student, formerly Teacher in  
Health Education  
Edward L. Bernays, 1 Wall Street, New York,  
N. Y., Counsel on Public Relations  
Ethel M. Hanson, 2525 Euclid Ave., Cleve-  
land, O., Head, Health Education Dept.,  
Cleveland College  
George H. Hoxie, M.D., Kansas City, Mo.,  
1000 Rialto Bldg., Medical Director, Kansas  
City Tuberculosis Society  
Fred C. Mills, Boy Scouts of America, 2 Park  
Ave., New York, N. Y., Director of Swim-  
ming and Water Safety  
Izetta North, 1337 N. University Ave., Ann  
Arbor, Mich. (Assoc.)  
Armin A. Roth, 966 Washtenaw, Ypsilanti,  
Mich., Student, formerly Instructor in  
Health Education  
Alma L. Wingeier, 1507 Wells St., Ann Arbor,  
Mich., Student, formerly Instructor in Phys-  
ical Education

### *Public Health Nursing Section*

Helen C. Manzer, R.N., 10 Sheridan Sq., New  
York, N. Y., Executive Officer, Comm. on  
Health, New York Principals Assn.  
Mary Murphy, R.N., 1638 E. Wheeling Ave.,  
Cambridge, O., Metropolitan Life Ins. Nurse  
Maxine E. Owens, R.N., Fayetteville, W. Va.,  
Public Health Nurse, Fayette County  
Elizabeth I. Rood, R.N., 440 E. 26th St., New  
York, N. Y., Head Nurseship, operating  
room, Bellevue Hospital  
Mrs. W. J. Ross, R.N., 10 Orchard St., Wades-  
boro, N. C. (Assoc.)

# PUBLIC HEALTH ADMINISTRATION

**The Objectives in Public Health Nursing**—The National Organization for Public Health Nursing has issued a tentative statement outlining the range of public health nursing services and its various aspects. It is hoped that this may serve as a measuring stick for the appraisal of individual nursing service. Health officers have long sought a means of measuring the objectives of nursing service and of appraising their own departmental work.

The general objectives of all public health nursing services are:

1. To assist in educating individuals and families to protect their own health
2. To assist in the adjustment of family and social conditions that affect health
3. To assist in correlating all health and social programs for the welfare of the family and community
4. To assist in educating the community to develop adequate public health facilities

The objectives of public health nursing in relation to the various phases of the community health program have been enumerated for each of 12 functional divisions including: (1) Maternity, (2) Infancy, (3) Preschool, (4) School Age, (5) Adult Health, (6) Morbidity, (7) Communicable Disease, (8) Tuberculosis, (9) Venereal Disease, (10) Mental Hygiene, (11) Orthopedic, (12) Industrial Nursing Service.

(Ed.—Detailed objectives are here given for but one of these services.)

The objectives of the maternity nursing service are:

1. To get in touch with all prospective mothers as early in pregnancy as possible
2. To see that they are provided with both medical and nursing supervision throughout the maternity cycle
3. To instruct mother and father in maternal hygiene\* and infant care.

4. To instruct in the preparation for delivery

5. To arrange or provide nursing assistance during delivery

6. To provide or supervise adequate nursing care to mother and to new-born baby

7. To secure physical examination of new-born baby

8. To secure medical examination for the mother

Objectives in Public Health Nursing, *Pub. Health Nurs.*, 23, 9: 439 (Sept.), 1931.

\* Throughout these Objectives, "hygiene" implies the whole meaning of the term, e.g., physical and mental hygiene.

**Rural Health Organization**—In June, 1930, there was held at Geneva, under the auspices of the League of Nations Health Committee, a Conference on Rural Health Organization in Europe. The committee considered (1) guiding principles and suitable methods for insuring effective medical assistance in rural districts; (2) the most effective methods of organizing the health services in rural districts; (3) the sanitation of rural districts: the most effective and economical methods.

The findings and recommendations of the Conference were set down in a number of resolutions describing guiding principles and statements of fact. The Conference believed that 2,000 is the maximum number of persons who can be given proper medical attention by a duly qualified medical practitioner. In Germany it has been found that there is one physician to 2,317 persons in rural districts while in cities the proportion is 1 physician to 786 persons.

There should be available for the rural population, centers for diagnosis and specific treatment, suitably equipped and provided with a qualified staff.

There should be facilities for hospitalization and it is recommended that there should be a hospital for a population of from 20,000 to 30,000 people with about 2 beds per 1,000 of population and a minimum of 50 beds for any one hospital. There should also be provision for laboratory services and the utilization of medical specialists.

With regard to public health services, there are two principal forms of rural health organization: the form in which the state administers the local services, and the form in which the state has only supervisory functions, the local authorities being responsible for the local health administration. The optimum size of a rural health district would vary with the density of population and local disease conditions but in general should be from 20,000 to 100,000 with an average of 50,000 population. The minimum staff for such a rural health district should consist, in addition to the health officer, of 1 or more public health nurses, a sanitary inspector, and a clerk. The sanitary inspector should receive suitable training at an institute of hygiene. The services of a sanitary engineer should be made available either by the local official or by the central health organization.

It is not deemed possible to recommend a model budget for a rural health district. Funds may be derived in varying proportions from the state or from the local district. Collaboration with the medical profession and private health agencies is strongly urged.

(This publication can be obtained through the World Peace Foundation, 40 Mt. Vernon St., Boston, Mass.)

European Conference on Rural Hygiene, League of Nations, 1931.

Montreal, Canada—One of the features of the Montreal Health Department report of 1930 is an account of mental hygiene work in the Catholic schools. The work has not been started

in the Protestant School Commission, but an agreement has been concluded between the Department of Health and this Commission to begin the work after the holidays in 1931. The staff consists of 3 psychiatrists and 3 psychologist nurses.

The program consists in giving special examinations to detect abnormal children, to place them in auxiliary classes where special pedagogical and technical training will be given. If the number is large enough, it is stated that special schools should be organized in addition to the special classes. It is anticipated that a special institution, like the one in the district of Quebec, should be provided for children needing this type of care. The committee on mental hygiene has received the support of school authorities in this undertaking.

During the year, 9,069 children received 3 immunizing doses at intervals of 3 weeks of anatoxine Ramon, and 5,060 were given subsequent Schick tests within 4 to 6 months. In addition to immunization work done by the department of health in its baby clinics and among school children, the child welfare association immunizes in the 13 baby clinics under its management. The "Federation d'Hygiene Infantile" carries on this work in its 18-baby clinics, as does the "Ecole d'Hygiene Sociale Appliquée." The City of Montreal supplies the anatoxine and Schick test material provided the organizations follow the methods of the department of health and report all cases immunized.

Shorewood, Wis.—Shorewood, with a population in 1930 of 13,500, reports that 2,844 pupils, or 91 per cent of the school children of the community, received health examinations during the year and that of this group 28 per cent were found to have "correctible defects." Of those children having defects, 65 per cent received treatment. In one school, 1 per cent of the chil-

dren were found to have cardiac defects of an organic nature and were referred to the family for their doctor's opinion. The functional heart cases, 52 in number (1.9 per cent), are kept under observation and restricted from competitive games unless the family physician advises otherwise. They are reexamined at 6-month intervals, or oftener when indicated.

The policy regarding health examinations is to examine all athletes for competitive sports at the beginning of each school year, to recheck all known heart cases, to examine the new students entering schools, and give a routine heart examination to all pupils.

As the examination of pupils in a schoolroom is completed, a typewritten report of the findings is sent to the teacher in order that children with sight or hearing defects may be given special consideration in seating, and to secure coöperation and interest in obtaining corrections and an intelligent understanding of the handicapped children. The family, by note, telephone, or home call, is notified of any defects found.

It has been the practice for a nurse or physician to visit each school every morning and afternoon for the purpose of inspecting absentees and to exclude from school any children with symptoms of illness. Temperature is taken of each child inspected. No treatment is given in school except first aid in emergencies.—Annual report of the health commissioner, Shorewood, Wis., 1930–1931.

**Pasadena, Calif.**—The annual report of the Pasadena Health Department for the fiscal year ending June 30, 1931, is built around the *Appraisal Form for City Health Work*, and shows a rating of 817 out of a possible 1,000 points for the health work of the city. On the basis of a population of 76,210, the expenditures of the health department amount to \$.80 per capita, while

expenditures of other agencies for health total \$1.76, including dispensary and preventorium service. In the Inter-Chamber Health Conservation Contest, Pasadena received honorable mention.

This city operates under the city manager plan, and the health officer is appointed by the city manager for an indefinite term, on a full-time basis. Upon the request of the health officer an advisory committee on public health was organized, consisting of 3 physicians, appointed by the Medical Society, plus a representative each from the Woman's Civic League, the Visiting Nurse Association, the superintendent of the hospital, and the Community Chest.

The city has been divided into districts and the nurses and sanitary inspectors under their respective chiefs are responsible for these districts. The only exception to this policy is in meat and milk inspection. "Nurses and inspectors are impressed with the fact that their work is educational as well as supervisory."

**Los Angeles County Health Department, Calif.**—According to the annual report of the Los Angeles County Health Department for the year ended June 30, 1931, marked improvement has been made in the general management of the department. The creation of the position of business manager and necessary office assistance to set up proper bookkeeping, accounting records and statistics, as recommended in the health survey report of 1928,\* have enabled marked economies to be effected. The budget is broken up by function, and by district, and an adequate control system through proper internal forms and requisitions is maintained. Monthly balance sheets are now available to the

---

\* This survey was made for the Los Angeles County Bureau of Efficiency at the suggestion of the County Health Officer by Ira V. Hiscock and Harry F. Scoville, under the auspices of the Committee on Administrative Practice of the American Public Health Association.

executive as well as detailed reports on expected liabilities.

The total expenditures in 1930 amounted to \$1,218,064, or 4.1 per cent less than in 1929; yet the amount of floor space increased 31 per cent, the medical work in clinics 33 per cent, and communicable disease cases handled 45 per cent over the previous year. The health department served an area with a population of 705,000 in 1930 at a gross per capita cost of \$1.72. The contract system of service with cities necessitates a daily time-sheet showing distribution of all work by location as well as character. Each city is given a detailed cost report annually. This work is done through the Hollerith system of punching cards from the daily service data, the sorting and tabulating being done by electrical machines. Segregation of costs by function is also thus secured economically. Special unit cost studies are also being made.

A committee was created during the year to bring together the demands of the field and health center services with the central office administration. This committee, known as the standardization committee, considers all new forms of procedures requested or inaugurated in the department. It also attempts to standardize supplies and equipment with the aim in view of eliminating excessive waste. This mimeographed report of 207 pages contains much interesting administrative information, attractive cuts and architect's floor plans of the health centers, and many statistical charts and graphs which relate to finances as well as to vital statistics.

**Anderson County, S. C.**—The ninth annual report of the Anderson County Health Unit for the period ending September 30, 1930, contains among other interesting features an account of a pellagra clinic held at the health unit offices where examination of patients and complete histories were made and diets

were outlined. One hundred and fifty-eight patients with pellagra received instruction during the year. Pellagra is considered one of the serious public health problems of the area.

**Akron, O.**—A portable milk testing truck, built by the Dairy and Food Division of the Department of Health, was put into use the first of the year 1930. The farmers' milk is tested on this truck for sediment and keeping qualities at the pasteurizing plant before it is unloaded, and that which is below standard and condemned is not mixed with the other milk in the plant. This procedure has aided both the farmers and the consumers. One plant reported that in previous years, during hot seasons, they often returned, because of souring, as many as 200 to 250 cans of milk a day, while in 1930, during a similar period, they returned but 10 cans.

During the year the eradication of tuberculosis among cattle of the county and territory supplying Akron was completed and the county became "accredited." Over 98 per cent of the milk supplied to the city is also pasteurized. —*Annual Report, Dept. of Health, Akron, 1930.*

**Kanawha County Health Unit, W. Va.**—Through the educational system, the county health unit has been able to interest the Parent-Teacher Associations and Women's Clubs in participation in the public health program in a constructive manner. They have been the means of bringing together large numbers of parents and their children in various places throughout the county for health conferences, where members of the health unit meet for the purpose of teaching prenatal care, furnishing instruction to promote infant, preschool and school hygiene, giving instruction regarding communicable disease control, and providing artificial

immunization against typhoid, diphtheria, and smallpox. "We believe these conferences have had a most enduring effect and an educational value on account of the practical demonstrations."

There were 84 conferences held in schoolhouses during the school term and also during vacations, with an attendance of 13,000. Complete immunizations against typhoid fever numbered 7,201, against diphtheria 4,098, and against smallpox 4,538. The larger and more populated communities are said to have been previously immunized and hence the numbers protected in 1930 were smaller than for the previous year.—*Fifth Annual Report*, Kanawha County Health Unit, W. Va., fiscal year ending June 30, 1931.

**Hygienic Institute, Illinois**—The activities of a full-time district health program for La Salle, Peru, and Oglesby, Ill., made possible through an endowment plan, are described in detail in the 16th annual report of the Hygienic Institute. The population served approximates 28,000 and the budget for the last fiscal year was \$39,000. Besides the income from endowment, each of the cities contributes to the budget. Other sources of revenue are the Tri-City Tuberculosis Society, Metropolitan Life Insurance Company, State Department of Public Health, fees from bedside nursing, and the handling of vital records. Through identical city ordinances, the executive head of the institute, known as director, has always been

selected as health commissioner of each city. Each city also has a board of health, which consists of the commissioner of public health and safety, the chief of police, and the health commissioner.

The personnel of the Institute, besides the Director, consists of a bacteriologist, a sanitary officer, a chief nurse, and 6 staff nurses, a stenographer-clerk, a general service man, and 5 clinicians. The institute maintains a medical library for the use of the physicians of the three cities, and partially supports a hospital for the isolation of communicable diseases. "Modern public health discoveries and practice have so greatly reduced the need for such hospitals in the smaller cities that but 3 patients applied for admission during the past year. These consisted of 1 case of erysipelas, and 2 cases of scarlet fever."

An arrangement has been worked out with the Tri-City Medical Society, whereby the physicians vaccinate the school children for a small consideration, and the Institute has inaugurated pre-school clinics, at which toxoid for the prevention of diphtheria is given. In 1929 and 1930, the city of La Salle received honorable mention in its population class, in the Inter-Chamber Health Conservation Contest of the U. S. Chamber of Commerce.

This interesting report of 67 pages is well illustrated with photographs and statistical charts and tables, and is worthy of study by public health administrators.

# LABORATORY

## ACCURACY OF COUNTING AN AGAR PLATE \*

DR. F. L. SCHACHT AND DR. A. H. ROBERTSON

*New York State Department of Agriculture and Markets, Albany, N. Y.*

UNLESS the agar plate is counted accurately, the bacterial analysis is worthless. Each analyst must answer the question when counting a plate, "Shall I count this colony or not?" *Standard Methods of Milk Analysis* states that all recognizable colonies shall be counted.

During 1930 four counting contests were conducted. Thirty-five individuals counted one or more plates. One or more of 17 different combinations of counting equipment were used. A total of 38 plates were counted and 1,543 duplicate counts recorded. At each contest a system was usually followed in

FIGURE I—FREQUENCY POLYGON OF PERCENTAGE VARIATIONS BETWEEN DUPLICATE COUNTS AMONG THE 7 ANALYSTS AT THE SYRACUSE PLATE-COUNTING CONTEST. EACH ANALYST COUNTED 49 PLATES IN DUPLICATE.

\* This article was prepared by the authors, from the Annual Report of the New York State Department of Agriculture and Markets, 1930—Editor.

which 6 people counted 6 plates in duplicate, using 6 different counting devices, making a total of 72 counts on

\* The number of counts averaged depends on the number of individuals and the number of counting devices as given in columns 3 and 4. The individual mean count is calculated regardless of device used and the device mean count is calculated regardless of individual who counted.

† These excessive variations in this column may be explained in some cases by the lack of familiarity of the worker with the counting device and in others by an unsatisfactory apparatus. The results secured on the same apparatus, particularly if a satisfactory one, are much more consistent.

FIGURE II—A SATISFACTORY HOME-MADE PLATE-COUNTING DEVICE

each plate. A slight modification of this plan prevailed in some cases. From this information the individuals as well as the devices which gave consistently the highest and lowest counts were determined. The ability of the individuals to duplicate their counts was measured also.

The variations between individuals' counts on the same plate regardless of device used are summarized in the fifth column of Table I. The next column summarizes these variations from the standpoint of the device used regardless of the individual who counted. It is very difficult to draw sharp lines defining the variability attributable to the individual or to the device. Our opinion that the personal equation offers the greatest source of error is founded on the observation that only on 6 of the 38 plates were the percentage differences among individual's means less than 15 per cent, and 37 per cent of

them were greater than 30 per cent. In contrast to this, 37 per cent of the percentage differences among device's means were less than 15 per cent and only on 9 of the 38 plates were the percentage differences greater than 30 per cent. Furthermore, a comparison of the percentage variations reveals that in nearly two-thirds of the cases, those based on the means for the individuals exceed those based on the means for the devices. Figure I graphically reveals the extraordinary wide differences among some individuals and the amazingly small differences among others when their duplicate counts, using the same device on the same plate, were compared.

The causes of error in counting are (1) failure to know what to count, (2) failure to see the colonies, and (3) carelessness. The use of a device whereby illumination can be secured from the two opposite sides and in

which the lens is held at a certain distance from the plate seems to give the most satisfactory results. A pasteboard Wolffhuegel guide plate is preferred to a glass one on account of the glare caused by artificial illumination. The count is relatively more uniform and much higher than those secured without artificial illumination. Lower counts have been secured when the engraver's lens which magnifies  $2\frac{1}{2}$  diameters was used both with and without artificial illumination. Figure II shows an instrument which has given satisfactory results. There may be other

instruments on the market which will give more accurate results, but in the interests of uniformity as well as practicability, it is felt that some modification of the one shown in Figure II will be satisfactory.

The results of the contests also indicate that individuals should be able to duplicate their own counts on the same plate within 5 per cent and that they should duplicate the results of others on the same plate within 10 per cent. A few of the laboratory workers have demonstrated their ability to do this.

## VITAL STATISTICS

**Abortion in Austrian Hospitals—**Interest in the declining birth rate, together with the problem of abortion, led to an inquiry by the Austrian Public Health Service into the 9,000 cases of abortion which occurred during 1929, chiefly or entirely in the hospitals of this country. While this number is not identical with the actual number of abortions in Austria it is sufficiently large to be representative, and to serve the purposes of the inquiry which were to show the dangers associated with miscarriage, and to gain an insight into social conditions.

The largest number of cases of abortion occurred among unmarried women of the age groups 21-25, and among married women of the age groups 26-30. The abortion occurred in 80 per cent of the cases in the 2d and 3d months of pregnancy, no difference being observable between married and unmarried mothers. In 9.6 per cent of the abortions, pathologic sequels developed; in Vienna alone, the proportion

was more favorable, 5.9 per cent. The case mortality was 0.75 per cent (Vienna, 0.60 per cent), another proof that the care in the city hospitals gives better results. However, inquiries in the gynecologic departments revealed that the figure 9.6 for the percentage of patients suffering from after-effects of abortion is much too small.

From the personal histories of patients in any hospital of the kind, one can find in much more than 10 per cent the anamnesis that the present disorders are traceable to a previous abortion. Many cases of chronic endometritis and parametritis remain long latent. Also menstrual and other disturbances must frequently be ascribed to a former abortion.

In the 9,000 cases, death ensued in only 0.75 per cent, whereas in the combined statistics of hospitals among the causes of death, as affecting the patients in general, abortion is put down at 2 per cent. According to general statistics, as well as from the study of the

9,000 cases, it is revealed that especially the first pregnancy results in abortion (about 25 per cent).

It is not so rare for women to have from 10 to 12 abortions; indeed, there were in this series of 9,000 cases two women in whom 15 miscarriages and one woman in whom 16 miscarriages were observed. As to whether sterility is a frequent result of injuries due to abortion, only more extensive statistics can decide; but there are many indications that such is the case. It must be emphasized that these statistics, published for the first time, can lay no claim to completeness. They include not more than 10 per cent of the abortions in Austria and are to be taken as a first attempt toward the solution of this problem.—*J. A. M. A.*, 97: 1478-1479 (Nov. 14), 1931.

**Tuberculosis Mortality and the Decline in the Birth Rate**—Among 15 states those that show a more than average decline in the birth rate tend to show also a more than average decline in their mortality from tuberculosis; those with a relatively small decline in their birth rate have likewise a relatively small decline in tuberculosis mortality. For instance, in Germany the birth rate between 1913 and 1928 fell from 27.5 to 18.6 per 1,000. The death rate from tuberculosis fell from 14.3 to 8.8 per 10,000. In Japan the birth rate over the same period was virtually stationary, and the decline in tuberculosis mortality negligible. The same parallelism can be shown in cities, and is illustrated by the statistics of Paris and Berlin.

With the fall in the birth rate the high point of tuberculosis mortality among women of childbearing ages has shifted back from ages 30-39 in 1896 to 20-24 in 1926 (statistics from Prussia). This change, it is suggested, is related to the earlier period of life at which, owing to the fall in the birth rate,

childbearing ceases.—O. Glogauer, *Tuberkulosesterblichkeit und Geburtenrückgang*, *Ztschr. f. Tuberk.*, 60: 7-15, 1931; *Bull. Hyg.*, 6: 681 (Sept.), 1931.

**Maternal Mortality in Holland**—Although according to official statistics Holland counts among the countries with the lowest maternal mortality, since the period 1916-1920, a considerable increase in the death rate has been noticed. The mortality following infection was about 7 per 10,000 confinements. The total mortality after confinements was 20-30 per 10,000. These figures were obtained from various local sources and corresponded on the whole with official statistics. It was difficult to find with certainty how this rise of mortality was brought about, but an important part may have been played by an increase of the number of miscarriages or induced abortion and sepsis, by a relatively larger number of primiparae and possibly by late marriages.—D. G. Wesselink, *De kraamvrouwensterfte in ons land*, *Nederl. Tijdschr. v. Geneesk.*, 75: 1555-1565, 1931; *Bull. Hyg.*, 6: 672 (Sept.), 1931.

**Inquiry on Infant Mortality in Chile**—An investigation of infant mortality in Chile included the following districts: Santa Ana (urban) and Hipodromo Chile (suburban), in Santiago; San Bernardo, a small village, and San Isidro (rural), contiguous to Quillota.

The districts of Santiago and San Bernardo have common characteristics: They are situated at 520 and 573 meters, respectively, above the level of the sea and have an exceptionally mild climate, with an average temperature of 13.8° C. (56.8° F.); frequent rains in winter and none in summer. The two districts of Santiago have a supply of pure water drawn from the Laguna Negra, which has a capacity of 100,000,000 cu. m.; both have a water carriage system of drainage. The district

of Santa Ana, with a population of 47,800, is divided into two sections. The southern section is composed of a wealthy or semiwealthy population; the northern section is principally inhabited by a poor, uncultured people, living in miserable, unhealthy conditions. The Hipodromo Chile District, with a population of 32,100, covers an area 4 times as large as the aforementioned district.

In December, 1927, the town of San Bernardo had a population of 10,296, a birth rate of 46.72 per 1,000 inhabitants, an infant mortality rate of 274.4 per 1,000 live births and a general death rate of 27.08 per 1,000 inhabitants. With climatic conditions similar to those of Santiago, it has an inadequate supply of excellent drinking water, drawn from the stream "El Canelo"; it has no sewerage, the drainage water going to filtering cesspools. Hygienic conditions are generally poor; poverty is prevalent, though not to such a degree as in the larger towns.

San Isidro, a rural district in the Department of Quillota, had a population of 4,600 inhabitants in December, 1927; a birth rate of 43 per 1,000 inhabitants, an infant mortality rate of 267.7 per 1,000 live births and a general death rate of 33.2 per 1,000 inhabitants. The average temperature is 14.2° C. (57.5° F.). The water supply is poor, pollution being made possible through the refuse water which is usually spilt in the street channel or on the ground.

Infant mortality during the first month, and particularly during the first week of life, which includes more than a third of all deaths, is generally due to obstetric traumatism and prematurity. Digestive diseases account for 28.2 per cent of all deaths, and acute respiratory diseases cause 26.2 per cent, the rate being higher in summer than in winter, probably because of the daily variations in temperature, which sometimes reaches 15.2° C. (59.5° F.) in Santiago and 14.8° C. (58.6° F.) in Quillota. Con-

genital syphilis, which was present in about two-thirds of the cases of specific infectious diseases, caused 8.7 per cent of the total number of deaths; syphilis was also the greatest cause of stillbirth; this shows the need of strengthening antivenereal measures.—Louis Calvo Mackenna, *Bol. d. Inst. internat. am. de protec. a la inf.*, 4: 426, 1930; *Am. J. Dis. Child.*, 42: 937 (Oct.), 1931.

**A Study of the White and Negro Infant Mortality in Maryland, 1916–1930 Inclusive**—A study of infant mortality in Maryland showed changes in the numbers and causes of deaths among white and negro infants, during the period 1916 to 1930 inclusive. The total experience has been considered in its entirety and has been divided into two periods of 1916–1923 and 1924–1930 for purposes of comparison.

The trend of birth rates in both the white and negro populations of Baltimore City and the counties has been downward. The mean rate per 1,000 population in the state for the period 1916–1923 was 23.94 for the total population, 23.37 for the white, and 26.73 for the colored population. For the period 1924–1930 it was 20.37 for the total population, 19.49 for the white, and 24.63 for the colored.

The trend of infant mortality in all parts of Maryland has been downward. The mean rate for the white race in the state for the period 1916–1923 was 93.6; and for the period 1924–1930 it was 70.7, a reduction of 24.5 per cent. In the negro race, the mean rate for 1916–1923 was 174.0 and for the period 1924–1930 it was 130.9, a reduction of 24.8 per cent. The mean rate of infant mortality in Baltimore City during the 1924–1930 period was 27.4 per cent lower for the white race than in 1916–1923. For the negro, the reduction was 27.0 per cent. In the counties, while there was a marked decline, the decrease was not so great as in Baltimore

City. The reduction was 21.2 per cent for the white population and 21.3 per cent for the negro.

A study of the principal causes of infant deaths in Maryland shows a reduction in each of them for the white and negro races, with a few noted exceptions. When the rates for the second period are compared with those for the first, the only cause of death showing an increase for the white race was injury at birth (8.1 per cent).

In the two periods, little change is found in the infant death rates from premature birth and from "other diseases of early infancy." Congenital malformations and debility showed a marked change, with a reduction of 28.2 per cent in the white and 26.2 per cent in the negro race.

Respiratory diseases showed a reduction of 16.1 per cent in the white and 15.2 per cent in the negro population; tuberculosis alone showing a decline of 31.3 per cent in the rate for the white race, and 25.3 per cent for the colored.

The most marked decrease in infant death rates, among both the white and negro races in the state, occurred in the deaths due to gastrointestinal diseases,

with a reduction in the rates of 48.0 per cent for white infants and 41.3 per cent for the negro. These reductions are of special significance in view of the fact that this group of diseases is regarded as preventable and also because decreased morbidity from this cause results in a decrease of deaths from other causes. This reduction has been more marked in Baltimore City, where both white and negro death rates from this cause are lower than for the counties.

In 1930, the infant mortality rate for the white population of the state was 63.1 per 1,000 live births and that for the negro was 121.5, the rate for negro infants being almost twice that for the white race.

In both periods, the excess of the negro death rates is most marked for syphilis, tuberculosis (all forms) and the group of respiratory diseases. Injury at birth shows the least difference. In the period 1924-1930, the negro infant mortality is 1.7 times higher than the white in Baltimore City, and in the total counties the negro rate is twice as high as the white.—*Child Health Bull.*, American Child Health Association, 7: 206-211 (Nov.), 1931.

# PUBLIC HEALTH ENGINEERING

**Observations of Water Supplies of London and Paris**—A very brief description is given of visits to the water works of Southend, Kempton Park, London, and Ivry and St. Maur, Paris. At Southend the water is treated with lime and alum, agitated, settled, recarbonated and filtered. Lime is recovered and the surplus sold. Experiments on the addition of activated carbon to the water before filtration are being carried out. At the Kempton Park plant compressed air is produced by pressure from the high water tanks. Rapid sand filters have been introduced to increase the capacity of the slow sand filters.

At St. Maur the ozonization plant, which had to be put out of action during the war because of the cost of fuel, is still intact, and may be used again. Liquid chlorine and javel water (sodium hypochlorite) are used for disinfection at Ivry. Experiments with rapid filters are being made at St. Maur. All water used in Paris is now filtered and disinfected.—E. J. Bartow, *J. Am. Water Works Assn.*, 1931. From Summary of Current Literature, *Water Pollution Res.*, IV, 10: 333–334 (Oct.), 1931.

**Water Softening**—The disadvantages of hard water are discussed and the three methods of softening, namely, distillation, precipitation and base exchange, are described. Distillation produces a very fine soft water, and is sometimes used for treating boiler feed waters, but is too costly for general use. The precipitation method has a fairly wide application in industries where complete softening is not essential and where the skilled supervision necessary for regulation of dosage and prolonged storage are practicable. Plants may be

of the cold or hot type, the latter being speedier, requiring smaller equipment and giving better softening.

For correcting temporary or bicarbonate hardness, lime alone is used, while for permanent hardness, caused, for example, by calcium or magnesium sulphate, soda ash must also be added. The addition of sodium aluminate may accelerate the process and produce softer water.

Under optimum conditions the cold process reduces hardness to 4–6 gr. per gal., while the hot process reduces it to 2–3 gr. per gal. Base-exchange is growing in popularity because of its adaptability, efficiency (hardness is reduced to zero), simplicity of operation, automatic adjustment for water of varying hardness, and ease of regeneration. The zeolite used is a sodium aluminium silicate and softening is effected by the exchange of the sodium for calcium and magnesium in the water. The plant employed and its operation are described. The zeolite is regenerated by washing with a solution of sodium chloride. Apparatus for controlling and effecting regeneration is described and illustrated by a diagram.—Crane, Ltd., Montreal, *Technique*, 1931. From Summary of Current Literature, *Water Pollution Res.*, IV, 10: 342–343 (Oct.), 1931.

**The Water Resources of America: Work of the Geological Survey of the U. S. A.**—The administration and finance of the investigation of the water resources of America are discussed. The study of surface waters is carried on at gauging stations and consists primarily in the measurement of the flow of streams. Investigations on

ground water deal with its occurrence, quantity, quality, and head, its recovery through wells and springs and its utilization.

Research into the principles of ground water hydrology is in progress. New apparatus has been constructed by C. H. Au, for exploring leaky wells for salinity of water at all depths by the electrolytic method. Further investigations deal with analyses of the mineral contents of both surface and underground water.

Reference is made to reports on the production of electricity; consumption of fuel by power plants, developed water power of the United States, etc.—N. C. Grover, *Water & Water Eng.*, 1931. From Summary of Current Literature, *Water Pollution Res.*, IV, 10: 352-353 (Oct.), 1931.

**A Complete Treatment of Sewage from Packing Houses by Super-chlorination**—A plant for the separate treatment of packing house effluents at Austin, Minn., is described. The flow of concentrated waste (12 times as strong as domestic sewage) is 750,000 gal. a day. The waste flows through a grit chamber and preliminary settling tank, the scum from which is removed for soap recovery to a mixing tank where chlorine is added.

Another mixing tank follows, giving a total mixing time of 20-30 minutes. The secondary settling chamber gives a detention time of 3 hours. The sludge from both settling chambers is mixed, filtered and dried. Its market value for feeding is expected to make the plant self-supporting. The effluent is clear and odorless and the condition of the river has greatly improved since the installation of the plant.

Packing house odors are also controlled by this process, which should be specially suitable if the waste is finally to be mixed with domestic sewage. The method is much cheaper than treatment

by biological methods either separately or with domestic sewage.—H. O. Halvorson, *Am. City*, 1931. From Summary of Current Literature, *Water Pollution Res.*, IV, 10: 360 (Oct.), 1931.

**A General Review of the United States Bureau of Mines Stream Pollution Investigation**—The report contains general facts and information on coal mine drainage. Streams representative of mining areas containing bituminous coal with low to average sulphur content and with high sulphur content were studied, attempts being made to determine variations in acidity and seasonal variations in mine drainage. Not only do acid waters require neutralization and subsequent softening, but the chemicals used in these processes and remaining in solution in the water cause "foaming" and "priming" of boilers. Fluctuations in the volume and strength of acid wastes increase difficulties of purification. The gravity of the problem of mine drainage is illustrated by a reference to the Indian Creek law suit in Fayette County which resulted in the sealing of a number of mines.

Acid formation in coal mines is due to the oxidation of iron pyrites to soluble iron sulphate which on hydration and oxidation forms sulphuric acid and iron oxide. The amount of pyrites varies in different parts of a coal bed, causing variations in the acidity of drainage. Outside gob piles cause increased acidity as they are composed largely of pyrites thrown out when mining or cleaning coal.

The efficacy of rock dusting as a method for decreasing acidity by neutralization is discussed. Acid wastes are harmful to fish, for, besides being toxic, they reduce the oxygen content of the water and their irritating effect on the gill follicles may be fatal. More than 4 p.p.m. of mineral acids will kill trout. Deposits on the bottom of streams resulting from pollution inhibit

fish propagation. Non-acid coal mines are referred to.

It is suggested from experience of mines and from laboratory tests on iron sulphide that sealing of mines excludes oxygen and prevents acid formation.—R. D. Leitch, Report of Investigation, Dept. of Commerce, Bureau of Mines, April, 1931. From Summary of Current Literature, *Water Pollution Res.*, IV, 10: 361–362, 1931.

**The Water and Sewerage Works of Moscow**—Describes an inspection of water supply and sewerage conditions in Moscow undertaken for the purpose of reporting projects for extensions. The 1929 population of Moscow was 2½ millions and plans are being made to deal with a population of 6 millions by 1950. The development of the water supply is briefly described. At present this consists of a well system furnishing about 7 m.g.d. and a supply of about 60 m.g.d. from the Moscow river.

The filtration plant for the latter supply comprises pumping plants, 6 sedimentation tanks, with 10-hour retention period, 80 pre-filters treating about 49 m.g.d. per acre, and 22 slow sand filters, operating at 4 m.g.d. per acre.

A sanitary protective zone extends for 50 miles up the river above the intake and all villages, factories, etc., in the zone are under the supervision of officers responsible for their sanitation. The general control of water supply is in the hands of the Commission for Control of Drinking Water and Sources of City Water Supply, the constitution and functions of which are described. All works have well equipped laboratories and are strictly controlled by routine tests.

The author speaks very highly of the water works personnel and of the general appearance of the plants. All supplies in Moscow are metered. Careful studies have been made of the possi-

bilities for future extensions. Supplies from the Oka and the Volga have been considered but the method decided upon is to increase the supply from the Moscow river by impounding reservoirs on the river and its tributaries.

The sewerage and sewage treatment systems comprise a separate sewer system, pumping station, irrigation plants at Lublino and Lubertzy, and an aeration plant at Koguhovsky. The oldest plant at Lublino is seriously overloaded and about 1 m.g.d. are treated by settling and contact filters. The newer Lubertzy plant gives excellent results. These plants treat about 90 per cent of the total flow. Only part of the sewage is settled before being deposited on land but settling tanks and separate sludge digestion tanks are planned. There is an experimental biological plant at Lublino and an activated sludge plant and trickling filter at Koguhovsky, treating about 3½ m.g.d., is also regarded as experimental. The trickling filters are aerated by a forced air method and work at 8–10 times the customary European rates for strong sewage.—I. S. Walker, *J. Am. Water Works Assn.*, 1931. From Summary of Current Literature, *Water Pollution Res.*, IV, 11: 368 (Nov.), 1931.

**The Use of Active Carbons for the Purification of Drinking Waters**—Active carbons, their manufacture, properties and purifying effect are dealt with. The treatment is becoming more widely used for the purification of surface water supplies, and produces a perfect tasting drinking water. Sauer at Amsterdam first suggested the use of powdered carbons for removal of bacteria and purification of water.

Later Imhoff and Sierp used granular active carbon for the purification of the city of Hamm water supply and chlorphenol tastes were eliminated. The Hydraffin filter used, which contained about 6 tons of Hydraffin, is described,

the amount of water treated being 24,000-30,000 c.m. per day. Reactivation of the carbon is only necessary every 15 months. The filter is cleaned monthly by counter flushing and occasionally regenerated by steaming.

A similar filter to that used at Hamm has been installed at Dresden to eliminate tastes in the Elbe waters. This filter is illustrated by a diagram. At Magdeburg powdered carbon has been spread on the slow filters, but this has the disadvantage of offering great resistance to the passage of the water. Purification by the "stirring in" method of applying active carbon has been used with success at Southend. In the United States highly satisfactory results have been obtained from active carbon filters and their extensive future application is certain.

The use of activated carbon for dechlorination after superchlorination is dealt with. The process is a chemical reaction rather than one of adsorption, the chlorine reacting with water in the presence of active carbon to form hydrochloric acid which is neutralized by the hardness of the water. When the dechlorinating capacity of the carbon diminishes it may be restored by washing with a hot soda solution, to which chlorine may be added, after which neutralization may be effected with calcium chloride solution, calcium carbonate being formed.

The first large water works dechlorinating plant using carbon began operation at Aussig on the Elbe in 1930. This plant and others at Stuttgart and Ludwigshafen are described. For the removal of organic matter, more particularly humic acid compounds, aeration or biological treatment must precede active carbon treatment as saturation of the carbon is relatively rapid with organic compounds.

Resistance of carbon filters to water, choking of filters and their clearing

by counter-flushing or washing with dilute hydrochloric acid are described and the cost of active carbon treatment is discussed.—J. C. Liddle, *Water & Water Eng.*, 1931. From Summary of Current Literature, *Water Pollution Res.*, IV, 11: 372 (Nov.), 1931.

**A Field Method for the Estimation of the Salinity of the Water in Mosquito-Breeding Places**—In anti-malarial work, the bionomics of mosquitoes form such an essential part that such accuracy of information as is consistent with practicability is desirable. The author suggests a simple means of securing accurate information on the salinity of water. His scheme is the simplification of the ordinary water analysis technic for the estimation of chlorides in water.

Using a 10 c.c. pipette graduated in 0.5 c.c., the delivery point is cut off and the other end is sealed so that with the pipette in an inverted position, there will be an exact number of c.c. contained in the ungraduated portion of the pipette; that is, in the portion below the zero mark. The pipette thus prepared actually is the field test tube.

Two solutions of silver nitrate are prepared; one of such strength that a c.c. will precipitate 2 mg. of chlorine and another so that 1 c.c. will precipitate 10 mg. A saturated solution of potassium chromate is also prepared.

The technic consists of filling the tube to the zero mark with the water to be tested, adding 2 drops or so of the chromate solution, and then adding silver nitrate solution, a few drops at a time, until the yellow color disappears and a permanent faint red remains. The amount of silver solution used is then read off the graduations of the inverted pipette to the nearest 0.5 c.c. The parts of chlorine in the sample can then readily be calculated, taking into consideration, of course, whether the weak or the strong silver nitrate solu-

tion was used in the test.—J. A. Sinton and N. D. Kehar, *Indian J. Med. Res.*, 18, 1 (July), 1930. From *Public Health Eng. Abstr.*, XI: Ma: 5 (Mar. 7), 1931.

**The Sea Discharge of Sewage—**Report of a paper presented at the Royal Sanitary Institute Congress, July, 1931. The relative advantages of collection of sewage from the various places in a district and its discharge through a main outfall sewer into the sea, and of separate treatment for each place followed by discharge of the effluent into the river are discussed from the financial aspect and from the point of view of satisfactory purification. Besides the cost of construction of the outfall sewer the effect on the river flow of diverting the sewage flow must be considered.

The risks incurred in discharge of sewage into the sea, such as pollution of beaches, injury to boating, bathing and fishing, etc., are mentioned. The question whether the dilution of sewage by sea water will be sufficiently large and prompt to accomplish oxidation of sewage before it can be harmful or offensive is discussed. Rate of dilution can be investigated by observations of tides and currents as indicated by floats. The dilution of sewage in tidal rivers and on a flat beach is considered.

Except under the most favorable conditions, sewage should be screened before discharge into the sea. Screening, however, removes less than 10 per cent of the suspended matter, while if the sewer is long much less will be retained owing to disintegration during transit. Before arranging for discharge of sewage into the sea careful investigations should be made as disadvantages may outweigh advantages.—G. Thomson,

*Munic. Eng.*, 1931. From Summary of Current Literature, *Water Pollution Res.*, IV, 11: 389 (Nov.), 1931.

**The History of Sleeping Sickness in the Sudan—**This is an interesting account of the methods used to control sleeping sickness in the Sudan and the article should be read by those interested in insect-borne diseases.

It has been found that the most satisfactory method is to concentrate the sick people in villages or along roads adjacent to streams that can be kept clean and free from vegetation. This method makes use of the fact that wild and uninhabited country abounds in the fly carrier of the disease while concentrated groups under good surroundings and open streams are not invaded by flies. These measures were used to prevent the spread of infection rather than being aimed at the center of the epidemic.

The various superstitions of the people and their tribal customs were gradually overcome and adjusted to this new method of living and the task of extirpating a disease has in fact profoundly affected the life of the people. Up to the end of 1928 over 5,400 cases of sleeping sickness were treated in the Sudan. Where sleeping sickness had gained a footing a considerable epidemic was brought under control in the space of 2 years, and infection shut out from a district 5 times the size of Wales. The author considers the methods used to be effective and states that the epidemic lingered only where the medical and administrative staff was inadequate.—G. K. Maurice, *J. Roy. Army Med. Corps*, 55, 4: 241–259 (Oct.), 1930. From *Pub. Health Eng. Abstr.*, XI: Ma: 5 (Mar. 7), 1931. Abstr. H. A. Johnson.

## FOOD AND NUTRITION

The Effects of Radiant Energy on Milk Anemia in Rats—Two different types of radiant energy were compared in this experiment on rats suffering from nutritional anemia. The stock diet consisted of a commercial meal supplemented by lettuce, and the milk diet was prepared from commercial powdered milk in a solution containing 12.5 per cent of solids. Hemoglobin determinations and weighing of rats occurred once a week. The sources of radiant energy used were a "Pan-Ray-Arc" burning National Therapeutic A "Sunshine" carbons and an air cooled Cooper-Hewitt quartz mercury vapor lamp. A group of 16 rats were exposed to sunshine for  $\frac{1}{2}$  hour daily during June and July. Using the quartz mercury vapor lamp, the differences in hemoglobin between the irradiated and non-irradiated groups were not great. The mean value for animals surviving 10 weeks or longer is 8.29 gm. in irradiated animals, against 5.80 gm. in the controls. Irradiation with the flaming carbon arc resulted in hemoglobin values only equal to or lower than the controls. The group of rats exposed to sunshine had hemoglobin values in 7 weeks slightly higher than in control rats exposed only to subdued daylight, 8.4 gm. as compared with 6.7 gm. While the iron input was low, the rats were undoubtedly getting sufficient to maintain a balance at low hemoglobin levels. In some experiments, iron was added to the diet, but hemoglobin regeneration was no more rapid than in the controls. —Paul C. Foster, *J. Nutrition*, 4: 517 (Nov.), 1931.

**Viosterol and Cod Liver Oil—**  
In this study, viosterol was compared with cod liver oil on 3 groups of rats

on 3 different diets. In the first series, diet B consisted of a purified ration with 80 mg. of yeast; diet D, the same plus  $\frac{1}{2}$  drop of viosterol daily, and diet C the same plus  $\frac{1}{2}$  drop of cod liver oil daily. The rats were on this diet from 54 to 62 days. The average weight at the beginning was approximately 72 gm., and at the end of observation, 55.1 gm. on the B diet, 58.2 on the D diet, and 80.6 on the C diet.

Another series was run in which the B diet was supplemented with  $\frac{1}{2}$  drop of cod liver oil and  $\frac{1}{2}$  drop of viosterol daily after xerophthalmia developed.

Another series contained 3 variations of the diet, Bb, the ration plus 80 mg. of yeast daily; after xerophthalmia,  $\frac{1}{2}$  drop of cod liver oil and  $\frac{1}{2}$  drop viosterol daily, and diet Bc, the ration plus 80 mg. of yeast daily; after xerophthalmia developed  $\frac{1}{2}$  drop of cod liver oil daily, and diet B, the ration plus 80 mg. of yeast daily. The xerophthalmia was cured in an average of  $5\frac{1}{2}$  days on the modified diet. The D diet was comparable with the modified D diet in that  $\frac{1}{2}$  drop of cod liver oil was added daily after xerophthalmia developed. The second series of the experiment on the purified food was supplemented with 1 gm. of yeast daily and otherwise modified with viosterol and cod liver oil as in the preceding. The rats developed greater weight gains with the additional yeast but developed xerophthalmia except where cod liver oil was added.

Rats on the B and D diets in the second series showed pus in the nasal sinuses and abscesses on the tongue but not on the C diet containing the cod liver oil. The quantity of viosterol administered was alleged to contain the same antirachitic potency as cod liver

oil but this amount did not produce as good calcification. In the rats which developed xerophthalmia there were an inflamed respiratory tract, discolored liver, and spleen and other abnormal conditions of the organs. The addition of viosterol increased calcification of the bones but did not prevent or cure xerophthalmia.

The addition of cod liver oil not only cured xerophthalmia but produced a better calcification of the bones. The authors conclude as follows:

Since "colds," malnutrition and intestinal inadequacies are more frequent in children than rickets, this study emphatically suggests that the apparently widespread substitution of viosterol for cod liver oil in the diet of the child is not logical and may result in an appreciable decrease of the child's strength and resistance to infections.—

E. O. Prather, Jr., Martha Nelson, and A. Richard Bliss, *Am. J. Dis. Child.*, 42: 52 (July), 1931.

**Value of the Oyster in Nutritional Anemia**—Many other metallic elements besides copper have been studied in connection with hemoglobin regeneration in nutritional anemia with somewhat conflicting results, although a general agreement that both copper and manganese are effective in supplementing iron. The oyster contains these elements, with others, and in addition contains iodine, vitamins A, B, C and D. This experiment was undertaken to see how effective the oyster would prove as an anti-anemic food.

Rats were fed the Sherman diet consisting of whole wheat, whole milk powder, meat scrap and salt, containing 125 mg. of iron and 4.1 mg. of copper per kg. The average hemoglobin value for the experimental rats was found to be 11.79 gm. per 100 c.c. of blood. Rats were rendered anemic with commercial whole milk powder and sufficient water to reconstitute average milk.

In the period from 6 to 8 weeks the average hemoglobin value of the milk-fed diet had decreased to 5.68 mg. per 100 c.c. of blood, as compared to the stock ration at that time of 15.3 gm. The anemic rats were divided into groups.

Oysters from the South Carolina coast were shucked and dried in the laboratory and analyzed for copper, iron and manganese. Composite samples of dried oysters containing 892 p.p.m. of iron, 58 p.p.m. of copper, and 20 p.p.m. of manganese, were fed at a daily level of 0.56 gm., the highest dose, to 0.14 gm. the lowest. In addition, 3 concentrations of a hydrochloric acid solution of oyster ash were prepared, corresponding in iron, copper and manganese to the levels of the dried oysters. Both the dried and the oyster ash showed practically the same hemoglobin regeneration. The hemoglobin value on a maximum dosage rose rapidly with complete regeneration in 2 to 3 weeks. In 4 to 5 weeks, there was regeneration with the 0.28 gm. dosage. The 0.14 gm. dosage failed to restore hemoglobin to normal value.

At the end of the 8-week period, the average reached 12.0 mg. per 100 c.c. or approximately 80 per cent regeneration. In addition, a prepared solution of iron, copper and manganese resulted in approximately the same hemoglobin regeneration as when fed dried oyster or oyster ash on the same copper, iron and manganese basis.—Harold Levine, Roe E. Remington, and F. Bartow Culp, *J. Nutrition*, 4: 469 (Nov.), 1931.

**The Pellagra-Preventive Value of Canned Spinach, Canned Turnip Greens, Mature Onions, and Canned Green Beans**—In testing canned spinach, a California brand was used, and a daily allowance of 482 gm., including the can liquor, was permitted. A table gives the composition of the basic diet in each of the tests made. This spinach-supplemented diet was given to 16

colored female inmates of the State Hospital at Milledgeville, Ga. Fourteen of these remained under observation for 1 year and one developed symptoms of pellagra near the end of the 11th month.

The same test was made with canned turnip greens. In this experiment, 16 inmates were used, 15 of whom were under observation for 1 year. No symptoms of pellagra were observed.

A commercial variety of red onions was used. The dry outer skin was removed and the remainder chopped and steamed until done. Table salt to season was added. Each patient was given 525 gm. per day with the same basic diet as in the tests with spinach and turnip greens. Ten white female inmates were used. Five developed pellagra within 3 months. When the 5th case appeared the test was discontinued.

In testing canned string beans, 550 gm., including the can liquor, were given daily. Fourteen white female inmates were used, 12 of whom were under observation for a significant period. Two developed pellagra within 7 months, 1 during the 8th month, and 4 during the 9th month, at which time the test was discontinued.

It will be noted from these tests that canned green beans and mature onions are a very poor source of the pellagra preventive vitamin, while canned spinach and canned turnip greens, though not especially rich in it, are considered an important contributory source of this factor.—G. A. Wheeler, *Pub. Health Rep.*, 46: 45 (Nov. 6), 1931.

**The Effect of Partial Depletion of Vitamin B Complex upon Learning Ability in Rats**—Complete depletion of the vitamin B complex results either in beri beri or pellagra, and with partial depletion a nervous derangement may result in children and not in adults. While beri beri is prevalent in the Orient, it has occurred in Newfound-

land, Labrador and Norway, and is not confined to a rice diet. Flour and other milled cereals and highly refined foods are notably deficient in vitamin B complex, constituting a nutritional problem in the case of children.

With these facts in mind, an investigation was undertaken to study the effect of partial depletion of vitamin B complex on rats. The animals were depleted during the nursing period by depleting the diet of the mothers, during nursing, in yeast and wheat germ and feeding the young a diet first deficient in and later free from vitamin B complex.

Four groups were studied: (1) controls on normal diet, (2) depleted of vitamin B complex through the mothers' diet until weaning, (3) mothers on depleted diet but young on rich vitamin B diet, and (4) young depleted during the nursing period and from parents depleted of vitamin B in their early life. After weaning, the rats were given a vitamin-rich diet and the body weight brought near to the controls. After the controls were weaned, the growth was checked with a vitamin-B free diet for a brief period and then each group placed on the same diet of vitamin B-free food plus brewer's yeast.

After 21 days, or at the age of 70 days, the rats were trained in a standard maze once a day for a week and then required to run the maze once daily the first 3 days, then two trials daily until the problem was learned, the criterion being 8 correct out of 10 problems.

A brief summarization of the scores shows that the animals depleted of vitamin B through the mother's nursing diet were inferior to learning to the normal animals with large differences. The offspring of rats which were depleted of vitamin B complex in early life and again depleted during their nursing period were much inferior in learning ability. The offspring of depleted animals

on a vitamin B-rich diet showed adaptability equal to that of normal animals, suggesting that the learning ability of the second generation is not affected by early depletion of vitamin B of the first generation.

The offspring of animals depleted during the nursing period have a learning ability equal to that of the parents, indicating that the detrimental effect is probably not hereditary but traceable to the dietary factor.

Several references to the literature are quoted in which the dietary factor of

malnutrition in the nervous mechanism of children is discussed. These investigators believe that the investigations on children indicate a definite relationship between dietary deficiency and higher nervous functions and believe that with the prevalence of highly milled flours and refined cereals it is necessary that vitamin B complex should be supplemented in the diet of expectant and nursing mothers as well as of the infants and children.—Siegfried Maurer and Loh Seng Tsai, *J. Nutrition*, 4: 507 (Nov.), 1931.

# INDUSTRIAL HYGIENE

Medical Service of the Bell Telephone Company of Canada—The company occupies about 140 buildings in which questions of ventilation, heating, lighting, sanitation, etc., appear. In addition, it endeavors to ameliorate the home living conditions of its people through the method of instruction.

"Our Plan," as it is called, was inaugurated 15 years ago to cover medical services, sickness disability benefits, pensions, death benefits, etc. The endeavor is made to treat all employees alike. The medical work includes: First aid in which we are affiliated with the St. John's Ambulance Association, and the company now has 4,500 fully trained to render first aid anywhere; accident prevention work in which there is a continuous campaign and which has yielded remarkable results; and a health course for women leading to a certificate of proficiency, with quite satisfactory outcome.

Employees make no payment toward this plan or for any medical service rendered, although the company treats only minor and emergency conditions, referring usual sickness and fee arrangements to outside doctors. The plan provides for the payment of wages during sickness on a graduated scale (particulars given).

The medical department is under the direct supervision of the senior vice-president and comprises a medical adviser, a medical examiner in Montreal, and another in Toronto, all of whom are part-time salaried employees; 2 full-time nurses (although there are several other nurses engaged mostly in welfare work); 3 accident surgeons in Montreal and 3 in Toronto; and 120 doctors at other points in the company's territory, all paid on the basis of the work they

are called upon to do. Mutually agreeable arrangements are also made with outstanding specialists in various departments; e.g., X-ray, biochemistry, chest conditions, etc. These persons do indicated work, the expense of which is borne either by the employee or the company at the discretion of the medical adviser.

With this medical machinery there is maintained: (1) general supervision of sanitary matters throughout buildings; (2) the same in connection with construction camps, with the finest coöperation on the part of the provincial boards of health; (3) advice to all departments of the company, especially the legal and personnel departments; (4) examination and medical classifications of all applicants for positions—the 4-class system being used, viz., (*a*) those physically suited for the position desired, (*b*) those physically unsuited for the position desired, but able to be placed in some other kind of work—in which placement a benevolent attitude is maintained, (*c*) those physically fitted but who need surgical or medical aid to correct unsound conditions, and (*d*) those not physically suited for any position—in which experience has shown comparatively few cases occur and these unemployable people will probably have to be looked after sooner or later by the State; (5) the carrying of all accident cases to a conclusion; (6) coördination and coöperation regarding medical reports to attending physicians; (7) the making of physical examinations for outside physicians, using the special equipment which the company has, care being taken to observe all ethical considerations; (8) in the Montreal and Toronto areas, the perfection of arrangements whereby any employee may

apply for a medical examination and advice; and (9) the maintenance of service for minor medical or surgical conditions.

The author concludes as follows:

1. It is my belief that no industrial or commercial organization is justified in maintaining a medical service that is not financially profitable.

2. A well designed and well conducted medical service is a profitable venture for any company with 1,500 employees or over.

3. A fairly extensive experience has convinced me that such a service can be maintained without conflict with private practitioners, if reasonable ethics are practiced.

4. When a medical service is carried on along the lines indicated in my remarks, I believe it cannot fail to be conducive to public welfare.

—A. R. Pennoyer, M.D., Medical Director, The Bell Telephone Company of Canada. Abstract of paper presented before the Industrial Hygiene Section of the A. P. H. A. at the Sixtieth Annual Meeting at Montreal, Sept. 16, 1931.

E. R. H.

**The Significance of Industrial Health**—Perhaps half a century after the beginning of the modern public health movement, industry began organizing departments of preventive medicine. Industrial health is the fourth step in evolution of such services, being preceded by first-aid to the injured, a first-aid office within the plant, and compensation. We, as health officers, saw diseases against which we warred decreasing, in the list of the ten most important, but accidents gradually working their way to the top, yet recognized as preventable.

We are sorry that the National Safety Council developed its task so apart from health departments, as it could have learned more economically from our experience. In the field of education we had already been experimenting a long time so that we felt that the council and the health department

would have exchanged views and experiences with profit. Nevertheless, we are glad to have the council enter the field and we admire it for the success achieved.

Logically, after accident prevention came medical care in industry, and soon the realization that limiting oneself to the care of end-products is wasteful and prevention much more economical. Today industry has fewer rights with the employee than ever before in the history of society and the relations are becoming less personal and more on a basis of economics. This is more true of health than of other features. While we think industrial health loss is no mean item in figuring costs, employers are apt to think our judgment not well balanced and that health is magnified by us.

With the disappearance of the great epidemics of history, health people have not one basis left for an emotional appeal of great power and the public mind is not prepared to support health work on the basis of judgment. Here the intervention of industry is of almost priceless value and demonstrations by industry are motivating the situation. It is also possible for industry to require certain health practices and to secure coöperation in effecting them that cannot be otherwise accomplished. Its influences are also carried into the homes. Here it is practically impossible to maintain a line of demarkation between the workman and his family when it comes to applying the principles of prevention. Thus industrial health is significant from the standpoint of future health improvement.

The earlier tasks of health work are nearly consummated—communicable diseases. Shortly health work will be concerned chiefly with the degenerative diseases in the prevention of which persons and groups must change their habits and customs. Degenerative diseases result from the acts

and attitudes of the individuals concerned and prevention is much more difficult than the matter of fighting a microbe. Comfort or cost interposes to prevent action. It is also more difficult because well people are called upon to change their habits to prevent illness. Also, because what is done must be long continued.

The health forces will continue to need the example and help of industry, such as entrance physical examinations, periodic physicals, fitting men to jobs, and others. The proof that industrial health pays is regarded as non-conclusive by some employers, but it is necessary for efficiency of labor—and not for the regulation of death rates or even the lessening of sickness rates.—William A. Evans, M.D. Paper presented before the National Safety Council, Health Division, Chicago, Oct. 12, 1931.

E. R. H.

**Lead Poisoning in Brass and Bronze Foundries**—Thirty-eight men engaged in the founding of high lead (railroad) bronze were sent to the Montreal General Hospital for various complaints. Of these, 24 were found to be suffering from acute lead poisoning; 9 others showed definite evidence of lead absorption; and only 5 showed no signs of plumbism. Railroad bearing bronzes may contain lead up to 20 per cent.

Three brass polishers who succeeded each other on the same emery wheel became poisoned with lead. The amount of lead in the alloy was below 6 per cent.

Blood smears of 26 men engaged in the polishing of low lead brass and bronze (less than 6 per cent) were examined. Five of these showed stippled cells, well in excess of 200 p.m. red cell.

The analysis of air in one foundry showed the concentration of lead in the air to be about 0.85 mg. per cu. m.

Our review of the literature of chronic brass poisoning indicates that many cases of chronic disability occur among founders and polishers of brass, and that the symptoms recorded are closely allied to those of lead poisoning.

It is our belief that lead plays an important part in the disease picture variously diagnosed as brass poisoning, bronze poisoning, and copper poisoning.—Frank G. Pedley, M.D., and R. Vance Ward, M.D., *Canad. M. A. J.*, XXV: 299–303, 1931.

**Changes in the Ionic Content of Air in Occupied Rooms Ventilated by Natural and by Mechanical Methods**—This paper presents the results of a research conducted by the authors at the laboratories of Industrial Hygiene at the Harvard School of Public Health. It is pointed out that previous investigations have been unsuccessful in explaining the cause of the deadness, or lack of stimulating quality present in the air of occupied spaces.

The object of this investigation was to study the ionic content of the atmosphere in relation to ventilation and health. It will be recalled that the atmosphere consists of atoms, molecules and molecular groups (in addition to suspended dust particles) and that these elemental forms of matter are electrically charged either positively or negatively.

The ionic charges were measured by means of a modified Ebert apparatus.

Measurements of the ionic content of indoor and outdoor air disclose very definite seasonal trends; the content being much higher in summer than in winter; higher on clear days than on rainy or foggy days, and, as a rule, higher in the daytime than at night.

Studies of the ionic content of the atmosphere of small rooms showed that the content in unoccupied heated rooms did not differ much from that out of doors. In occupied rooms the ionic

content fell immediately as the room was occupied and this low level of ionic content was maintained until the occupants departed, after which a rise in ionic content immediately resulted.

A most interesting experiment was conducted in an attempt to determine the amount of air supply required to maintain normal ionic content (original content) in a crowded room. These experiments showed that 160 cu. ft. per person per minute was required in order to accomplish this end. A supply of 30 cu. ft. per person per minute did not raise the ionic content above the level attained with no ventilation.

The authors found it possible by artificial ionization to control the ionic content up to 10,000 ions per c.c.

(The authors of this paper are to be congratulated on a most careful and painstaking study in the field of ventilation research, and one which should be watched with considerable interest by persons associated with this field of endeavor.)—C. P. Yaglou, L. Claribel Benjamin and Sarah P. Choate, *Heating, Piping and Air Conditioning*, Oct., 1931, pp. 865–869. L. G.

**Manufacture of Leather Gloves—**This syllabus compiled by technically informed persons with a review of health hazards by Dr. C. P. McCord is devoted only to the making of leather gloves and does not include dyeing or leather tanning and dressing of skins and hides. The historical background of the industry, its extent and scope, and its present economic status (which is good despite the prevailing depression) are adequately discussed, while there is a section on conditions in individual plants.

The process of manufacture from the time when the skins arrive at the factory to their completion as gloves, including fur-lined gloves, is briefly described. The potential health hazards no doubt increased during the ages,

especially in the days when gloves were often termed "digitalia" (prior to the 11th century), but have been left largely behind with the tanner and dyer. There are still objectionable elements in glove making as a home industry, but such industry is subsiding. Nominal hazards only exist in modern glove making. A classification of jobs with their chief health and accident hazards is detailed.—Retail Credit Company, Atlanta, Georgia, *Indust. Rep.*, 6, 10: 111–124, illus. (Oct.), 1931.

**Quantitative Measurements of the Inhalation, Retention and Exhalation of Dusts and Fumes by Man: II. Concentrations Below 50 Milligrams per Cubic Meter—**In 1928 Drinker, Thomson and Finn reported a series of studies on the inhalation and retention of dusts and fumes of a concentration of from 50 to 450 mg. per cu. m. The present study was designed for the purpose of making similar determinations at concentrations less than 50 mg.

Briefly, the dust or fume was set up in an airtight chamber from which it was delivered by the subject's inhalation through a face mask, while the exhaled air was passed through an electric precipitator, thence to a spirometer for volume measurement. The dusts used were magnesium oxide and calcium carbonate. In all 422 experiments were conducted on 32 subjects breathing normally while at rest; mouth breathing while at rest; breathing normally during exercise; and during the inhalation of approximately 5 per cent carbon dioxide.

The authors conclude "the percentage of magnesium oxide retained during normal breathing while at rest varied from about 60 per cent at a concentration of 10 mg. per cu. m. to 45 per cent at 50 mg. per cu. m. The percentage of calcium carbonate retained under the

same breathing conditions varied from about 80 per cent at 10 mg. per cu. m. to 70 per cent at 50 mg. per cu. m.

The percentage retention for mouth breathing while at rest and for normal breathing during exercise and during carbon dioxide inhalation was about 10 per cent less than for normal breathing while at rest under the same conditions.

The percentage retention changed but little at concentrations above 50 mg. per cu. m., but apparently rapidly approached 100 per cent as the concentrations fell below 10 mg. per cu. m.—Carleton E. Brown, *J. Indust. Hyg.*, 13, 8: 285-291 (Oct.), 1931. L. G.

### Studies in Dust Retention: III. Factors Involved in the Retention of Inhaled Dusts and Fumes by Man

—In the previous study of this series it was found that the percentage retention of magnesium oxide and calcium carbonate dusts presented considerable variation, and the present study of the previous data was undertaken in an effort to determine the cause for these differences. In the present analysis the number of respirations, volume of respiration, minute-volume and vital capacity were analyzed, as well as the physical properties of the inspired dust and air, including particulate size and "wetability," and the relative humidity of the inspired air. Most of the author's summary follows:

1. Percentage retention is inversely proportional to respiration rate for rates below 20 per minute. An increase above 20 per minute is apparently followed by no change in percentage retention.

2. Percentage retention is inversely proportional to minute-volume of air breathed. This effect probably results from the increase in respiration rate with minute-volume.

3. Percentage retention is directly proportional to particulate size (not particle size) and to density of dust suspended in air.

4. Percentage retention is directly proportional to extent to which the dust is wetted in passing through water.

The results also show that percentage retention apparently is not affected by the following factors:

1. Volume per respiration.
2. Vital capacity.
3. Relative humidity of inspired air.

—Carleton E. Brown, *J. Indust. Hyg.*, 13, 9: 293-313 (Nov.), 1931. L. G.

**Injuries Produced in the Organism by the Discharge from an Impulse Generator**—The authors of this paper have set out to determine whether there is danger to life associated with the discharge of the impulse generator producing a current with a crest value of approximately 100 amperes at a maximum of 20,000 volts. Etherized rats were used as the experimental animal and in all 36 experiments were conducted. It was found that when the animals were placed on a grounded copper plate and the current was permitted to enter through the head, through the center of the back at the level of the scapulae or through the lumbar region, little or no damage was produced by the electric surge. In general it was found that when the surge was permitted to traverse the length of the animal, the heart continued to beat for but a short time or ceased beating immediately upon application of the current. Where the current entered in the skin of the dorsal midline of the mid thoracic region and traversed the animal to the tip of its tail, 3 rats survived and 1 died after breathing spontaneously for a few minutes. Similarly when the current entered one of the fore limbs and traversed the length of the body the heart, in most cases, continued to beat, although one of the animals died while others recovered.

It is concluded that the greater the portion of the body that is included in the path of the current, the greater the damage to the organism, and further

this damage is increased the greater the length of nervous tissue traversed by the discharge.

The present contribution, while brief, contains many statements which are not included in this abstract. Those particularly interested in the subject of electrical injuries are urged to refer to the original.—Orthello R. Langworthy and William B. Kouwenhoven, *J. Indust. Hyg.*, 13, 9: 326-330 (Nov.), 1931.

#### Warning Agents for Fuel Gases—

This bulletin presents the results of work done under a coöperative agreement between the U. S. Bureau of Mines and the American Gas Association. A copy of the agreement is included in the foreword, as well as the list of the gas companies and technical advisers concerned with the study.

After a discussion of the previous uses or suggested uses of warning agents, both in Europe and America, the types of these agents in respect to certain properties and a list of 93 compounds representing 36 different types were considered in the present investigation, carried on during the period of 1926-1930. Certain groups of substances were discarded immediately on the basis of such factors as toxicity, corrosion, or lack of stability. The intensity of the odor or irritating properties was measured for 57 substances which were thought to include the most promising agents. Eventually these were narrowed down to a few which appeared the most practical.

Neither pleasant nor unpleasant odors were found effective in waking persons unless present in very high and impractical concentrations. Eye, nose, and throat irritants were effective in practical concentrations. Most halogen-bearing compounds would appear unsuited because of corrosion of appliance parts, utensils, and household furnishings.

Ethyl mercaptan was found to be the most promising warning agent of the unpleasant odor type. While it is very effective in attracting attention and, when installed in city gas mains, was the cause of more complaints of leaks than any other material used in field tests, it was not found capable of awakening sleeping persons. Its very cheap cost was, however, a chief item in its favor. Amylene possesses an odor similar to manufactured gas and is rapidly transmitted to all places in the distribution system, but is not a commodity of commerce at present although it is estimated that its cost could be made similar to that of ethyl mercaptan. In fact, butylene, amylene, and Pintsch-gas condensate were transmitted through the distribution system very much more rapidly than the other substances tested.

Full scale and longer field tests in a number of different distribution systems are needed to procure the final answer for many different gas-service conditions that prevail in practice. In fact, final conclusions can only be made after practical trials are made in the industry over an extended period of years.

Crotonaldehyde was found to be second to ethyl mercaptan as the most effective compound for causing complaints of leaks in the field tests made. In these field tests, two cities having a population of 4,000 and 30,000 were used. The odorizing of natural gas with ethyl mercaptan was found not only to be practical for detecting certain types of leaks but much cheaper than usual inspection methods.

Odors are most valuable in giving immediate evidence of a contaminated atmosphere on entering a given premise, but nasal fatigue and temporary impairment or a loss of sense perception occurs rapidly. With irritants there is a lag in the sense perception which increases with the period of exposure; hence these are more satisfactory to indicate a gradual increase from low con-

centrations. For equal intensities, unpleasant odors were found to be far more effective than pleasant odors. Nose and throat irritants, including sternutators or "sneeze gases," were found in laboratory tests to be very effective in waking sleeping persons. In the end, investigators considered the field tests made too limited in both time and scope for final conclusions.—A. C. Fieldner, R. R. Sayers, *et al.*, U. S. Bureau of Mines, *Monograph 4*, 1931, 177 pp.  
E. R. H.

**The Toxicity of Methyl Chloride for Laboratory Animals**—In this research guinea pigs were exposed to concentrations of methyl chloride in three groups, averaging 49, 77, and 140 p.p.m. of the gas. The minimal lethal concentration of this gas for 72 hours' exposure of the test animals was found to be about 75 p.p.m. All of the animals exposed at 49 p.p.m. recovered, and all of the animals exposed to the average of 140 p.p.m. died. Food in the form of carrots exposed to methyl chloride absorbed traces of this gas but subsequent feeding of the carrots failed to produce symptoms in the guinea pigs. The most constant pathological changes were changes in the lungs and the meninges.—John L. White and Paul P. Somers, *J. Indust. Hyg.*, 13, 8: 273-275 (Oct.), 1931.  
L. G.

**The Rôle of Punctate Basophilia in the Control of Industrial Plumbism**—As a result of this study con-

ducted among workers in the electric accumulator trade the authors conclude that punctate basophilia (Sellers' method of staining) is often present in normal subjects and practically always present in workers exposed to a lead hazard. The value of punctate conditions in the diagnosis of plumbism is limited, but as an aid in the prophylaxis of plumbism, such conditions are of real value.—Ronald E. Lane, M.B., *J. Indust. Hyg.*, 13, 8: 276-284 (Oct.), 1931.  
L. G.

**A New Instrument for Measuring Cooling Power: The Coolometer**—Author's summary:

The paper describes a new instrument of great sensitivity for measuring the cooling power of an environment. Its essentials are a copper spool covered with a copper shell, the spool being wound with heating coils which constitute also an electrical thermometer operating on the null principle to hold the desired temperature. The current input when the desired temperature is reached gives the rate of cooling, when combined properly with the constants of the instrument. The instrument can be operated as a reflecting or a black body, and thus can be used to study radiation. With the reflecting surface it can be used as an anemometer. Its construction is such that recording devices can be applied. It can be operated dry, or covered with a wet wick.—Walter S. Weeks, *J. Indust. Hyg.*, 13, 7: 261-265 (Sept.), 1931. E. R. H.

# CHILD HYGIENE

**D**URING 1931 we have presented in these columns, from month to month, the elements which make up a complete child health program. Beginning with maternal and early infant hygiene the program was developed, one step at a time, until the child was well established in school life.

The reports from various committees of the White House Conference on Child Health and Protection have begun to appear and promise an encyclopedic array of material on every phase of child life. Now that this wealth of material is available, let us turn our attention to the actual developments.

This year we propose to address ourselves to the presentation of practical child health projects and organizations as they are actually set up and functioning in different parts of the country. It is hoped that members of the Association will send to the editor reports, organization plans, and current material relating to child hygiene in their communities.

We have just received a splendid report of the opening of a unique public school, in Battle Creek, Michigan, which aims to meet the needs—physical, mental and social—of all types of children. This is the Ann J. Kellogg School, made possible by a magnificent gift from W. K. Kellogg in memory of his mother, for whom the school is named.

The Battle Creek Public School Department has issued a bulletin concerning this school from which the following material is taken:

## FACTS ABOUT THE ANN J. KELLOGG SCHOOL

Battle Creek, Michigan

### *I. Purpose*

1. The purpose of the Ann J. Kellogg School is to bring equal opportunity to all

types of pupils for the development of those individual abilities which will enable each to meet most effectively the obligations of life.

2. The school was built in memory of the mother of W. K. Kellogg, whose proffer of a gift to the Battle Creek Public Schools made possible this institution. The building is pleasantly situated on a shaded residential street within a stone's throw of Ann J. Kellogg's first home in Battle Creek.

### *II. Building*

1. The building was especially designed for special education at a cost of one-half million dollars for site and structure.

2. Its dimensions are 318 ft. long x 190 ft. deep and is constructed in the shape of a capital "E."

3. The graceful lines, slate roof, and Indiana cut limestone front lend to its beauty and dignity.

4. All rooms are excellently lighted both with natural and artificial light.

5. The cafeteria is fully equipped for modern cooking.

6. There is an attractive library for all pupils of the school.

7. Eight class rooms for the lower grades are equipped with auxiliary industrial art shops.

8. The health suite consists of examining rooms, dental room, and office.

9. The model rooms for kindergarten and first grade pupils appeal to adults and children alike. Built between two class rooms, and with entrances from either, is a miniature house. The lower floor is an industrial arts shop and wardrobe, and contains a drinking fountain, lavatory, and toilets. The second floor is partitioned into two play rooms. Viewed from one class room this house presents an Old English front decorated with "Gingerbread," while from the other class room it has the front of a French house. A second equally beautiful and similar suite has a Spanish house on one side and a Colonial on the other.

10. The general shop for finding and exploratory courses is equipped for woodworking, mechanical drawing, clay modeling and firing, sheet metal work, electricity, household mechanics, and printing.

11. The gymnasium is spacious and well equipped.

### *III. Scope of Program*

1. The school is divided into three departments. Two of these, the elementary and

junior high, were organized for normal children and include the greater percentage of the pupils enrolled. The third is a department of special education.

2. The school's program and its objectives are inclusive of the ideals set forth in the recent White House Conference on Child Health and Protection. Organized around and coördinated with the two departments for normal children is a department of special education designed to provide for all types of atypical children. This organization was developed to make an analysis of the mental, physical, and emotional status of the children, to eliminate or minimize their handicaps in so far as possible, and to assist them in the discovery of their respective interests and aptitudes.

#### *IV. Special Rooms*

1. Adjusted program classes are provided for those pupils who experience difficulty with the academic phases of the regular class work. Special attempt is made to discover their outstanding aptitudes and abilities. The curriculum is not merely an abbreviated form of that used for the rest of the school, but is definitely selected on the basis of its present and future value in the lives of these boys and girls.

2. Home environment and physical health of children are important factors in their mental health and consequent social adaptability. Pupils who are unable to adjust themselves to life in a sufficiently satisfactory manner are placed in social adjustment classes. The program is designed to correct the maladjustment and to get them back into the normal groups as quickly as possible. The value of the work is demonstrated in the finer qualities of citizenship acquired by these pupils.

3. The lowered vitality group are placed in open air classes. Anemic, underweight, and malnourished children form a large percentage of the enrollment. They are provided with rest, milk, cod liver oil, "sunshine" treatments, and suitable physical exercise. They work and rest in rooms that are always kept as nearly as possible at a temperature of 69°.

4. The orthopedic section of the special education department is the most extensive of any on account of the equipment and personnel required for its administration. The hydrotherapy room is equipped for warm water treatments, and whirl pool and brine bath. The warm water pool is kept at 95° Fahrenheit and is used for the reëducation of paralyzed muscle. The buoyancy of the water supports the child sufficiently to make exercise much easier, and the heat stimulates

circulation and assists in relaxation. The use of the whirl pools is equivalent in effect to a general massage.

The psychology involved when children find that they can use their muscles in many ways that are new to them plays an important part in their progress.

5. Special lamps and bakers are used in the physiotherapy room for reëducation of muscles by heat and massage.

The physical therapy room is equipped with such apparatus as a punching bag, stall bars, spastic ladder, and mats. The room is used for corrective physical exercises.

6. The work in occupational therapy supplements that in physical therapy. The purpose is to provide therapeutic exercises that will be interesting and creative as well as remedial. It includes units in such work as sewing, weaving, cooking, clay modeling, typing, printing, wood work, and basketry.

7. Sunshine baths are furnished in a well equipped solarium. Reclining cots are arranged in a circle below the source of light. The light is radiated from four special carbon arcs suspended from the ceiling.

8. Proper eye hygiene and conservation of sight are the objectives of the sight-saving classes. Equipment used for this sort of work includes heavily outlined maps, 24 point text books, and special desks. To eliminate glare, the blackboard is tilted and the desks are of dull finish. No pictures nor anything including detail or likely to cause eye strain is used. Blind children and those whose vision is becoming worse, such as progressive myopia cases, will be taught to read braille.

9. Children who are so deaf that they are handicapped in attempting to carry on ordinary conversations are taught speech reading, or visual hearing. Congenitally deaf children are, of course, taught to do the same and also to speak. Moving pictures and other special equipment are used to develop in them the ability to use properly the various organs of speech and produce sounds which they themselves have never heard.

10. Speech correction classes have been included for those with such defects as lisping, stuttering, stammering, and cleft palate.

11. Specially gifted children often find the ordinary school work very monotonous. As a rule, these pupils are capable of carrying a greatly enriched program with no more effort than is required of the ordinary child to do the work of the regular grades. Organized into major work groups these pupils can learn to do dramatic work in foreign languages, creative work in music and art, and elementary experiments in science at very early grade levels. They also learn to assume

an initiative and responsibility that are compatible with their natural endowments.

12. There has been formed a special reading group for those pupils who experience severe difficulties in reading, but whose abilities are not otherwise retarded. This work involves diagnoses of the particular difficulties and private tutoring and drill to overcome them.

#### W. K. KELLOGG FOUNDATION

"The permanent headquarters of the W. K. Kellogg Foundation, which Mr. Kellogg launched with a large sum of money, are located in Battle Creek.

"The purposes of the Foundation are directly or indirectly to become actively engaged in child welfare, to consider ways and means of helping in matters of child health, education, recreation, character building, and to influence school children so that health education may in turn penetrate the school, the home, and the community.

"The Foundation's activities are not limited to any country, race, creed, or religion, or are they to be confined within any geographical boundaries.

"At the present time the Foundation is intensely interested in the problem of the rural school. It is encouraging the consolidation of small country school districts and the establishment of central schools to include all classes and grades up to university entrance, where vocational training and health courses may be added to the curriculum so that the rural school child may have equal, if not greater, opportunity than the urban child.

"Another of the projects of the Foundation is to sponsor the physical and mental health programs in the Ann J. Kellogg School.

"The work of the Foundation is not only carried on in close coöperation with the local medical profession, but as far as possible the services of local physicians are utilized.

"The medical work at the Ann J. Kellogg School is under the supervision of an Advisory Board representing the W.

K. Kellogg Foundation and the Board of Education. The members of the Advisory Board consist of:

Health Officer of the City of Battle Creek  
(Chairman)

President of the Calhoun County Medical Society

School Physician

General Chairman of Consulting Physicians  
whose services are used in the health program

Medical Director of the W. K. Kellogg Foundation

Local Representative of Crippled Children's Committee

Superintendent of the Battle Creek Public Schools

Principal of the Ann J. Kellogg School

#### PERSONNEL OF ANN J. KELLOGG SCHOOL

##### *Administrative Staff*

Principal

\* Director of Pupil Placement

\* Director of Health

##### *Teachers*

Elementary Department

Junior High Department

Special Education Department

Special Subjects

##### *Special Personnel*

Dentists

Visiting Teacher Nurse

Nurse

Physiotherapists

Occupational Therapist

Clerks

Dietitian

Librarian

Attendants

Bus Drivers

##### *Maintenance*

Engineer

Fireman

Janitors

##### *Superintendent's Staff Giving Part Time Assistance*

Director of Special Education

School Physician

Supervisors of Elementary Grades

Supervisor of Vocational Education

Supervisors of Industrial and Fine Arts

Supervisors of Music

Directors of Physical Education

*Consultants and Directors of Clinics*

This includes more than twenty specialists, representing local and state medical and dental organizations."

# PUBLIC HEALTH NURSING\*

**When Nurses Speak in Public—**  
Nurses need to realize that to be successful in public speaking they must be heard; otherwise the morale of their audience gradually wanes. Inability to be heard and lack of spontaneity often go together, and this is fatal.

Nowadays when a nurse is on some big program to speak she is requested to have her paper completed by a given date and forwarded to the committee. Busy as she is, with an intense effort she hurriedly completes it and sends it in, thankful that it is done. It would be better if she were allowed to send in a brief outline of her paper 3 months ahead, as an address should grow like Topsy; the ideas in it should expand and change as time and thought are spent on them. It pays to live intimately with one's subject, and a busy nurse has time to do this, dressing and undressing, waiting for a bus, going down town, or taking a walk. If the subject is allowed to ferment in the back of the mind often the stream of expression can scarcely be restrained. This is better than to sit at her desk and "torture her arid thoughts into a definite channel."

The chief objection to many papers read at nurses' meetings is that they do not arouse interest, stimulate curiosity, or make one think—they are not alive enough to make a dent in the placid surface of any mind.

Nurses are too afraid of changing their minds or expressing thoughts which are not in agreement with the conclusions of others, though they should know that change is essential to all growth.

After the outline of a paper there should be a rough draft to be analyzed as follows:

1. Is what has been written based on sufficient knowledge and study?
2. Is it honest in purpose and expression?
3. Is it animated by a desire to please or to conform to the opinion of others?
4. Does it express the meaning of its author?
5. Does it serve any useful purpose?—Is it helpful, instructive, stimulating, amusing, or interesting?

It helps a beginner to concentrate on arousing the interest of a bored looking person sitting on a back row directly in front of her. Some like to pick out a face showing kindly interest for the inspiration it gives.

It is a good thing for a nurse to be nervous for fear her address will be a failure. Complacency and assurance are not assets at all.—Mary E. Gladwin, R.N., *Speaking in Public*, *Am. J. Nurs.*, XXXI, 10: 1147-1152 (Oct.), 1931.

**Nursing Problems Are World-Wide—**There is a critical situation in nursing in the United States, in England, and in the Union of South Africa, but the situations are somewhat different. In England provincial hospitals are finding a shortage of properly qualified nurses to staff them; in the United States there is a great oversupply of nurses, many of them poorly qualified, while there are not enough well qualified public health nurses and instructors in nursing schools to go around; in the Union of South Africa there are not enough nursing schools to train an adequate supply of nurses.

Perhaps there is an underlying reason for these present acute nursing situations. In the 80's and 90's there were

\*The material is not to be used for other material to be published in the *Journal of Public Health Nursing*, L. F. Mac-  
Lennan, Editor, 1111 North Dearborn, Indianapolis, Ind.

few opportunities for young women of good cultural and social background and the new profession of nursing offered emotional satisfaction, opportunity for development and economic independence. Later hospitals increased and enlarged enormously and at the same time many other professions were opened to women. Hospitals continued to depend upon student nurses and continued the old militaristic system which served its purpose well when it was first laid down by Florence Nightingale.

An "Outsider," in the *Nursing Times* for October 17, says:

At one time the nurses of the day were as a rule nuns, and these nuns in mediaeval times were quite willing to submit to the rigorous discipline imposed on them. They had taken vows by which they had renounced all worldly things, but those same vows are not required from nurses today and yet in many cases the same discipline prevails.

If one compares the lives of two 18-year old girls, one training for the teaching profession, the other for the nursing profession, he soon realizes some of the reasons why the better type girl would rather choose teaching. She has the time of her life in college; she works hard but she has her own latch key, uses the telephone whenever she likes, and takes part in student social activities. She has freedom to develop individuality. In the nursing school, as an "Outsider" expresses it, she "is expected to renounce her own individuality for the next few years and become a little machine, efficient, but devoid of feeling except where it concerns her patients."

An "Outsider" also says:

There is probably no greater autocrat in the world than a hospital matron. She may not be outstanding in personality, education or social standing, but she can entirely forget the fact that she was once a probationer, and stand on a pedestal to which the whole nursing staff must look for several years.

Mary M. Roberts, editor of the *American Journal of Nursing*, in a let-

ter to the *Nursing Times* of the same issue, says modern young women of high type in England and United States are not devoid of the spirit of service. Many able and educated women can be and are interested in the nursing profession, but they are not living in the Victorian era, so they want, as do all modern young women,

Reasonable hours  
Adequate income  
Constructive leadership  
Opportunity for growth

We are quoting Miss Roberts as to the solution of the nursing situation:

When schools of nursing are organized and supported as other professional schools are now supported—by taxation or philanthropy—when student nurses pay tuition (part of this might well be remitted for service rendered), when hospitals have hours of service comparable to the hours of work of other young women of good intelligence, education and social background, we shall have gone a long way toward solving the problem of securing adequate, intelligent and sympathetic nursing service for our patients.

About Public Health Nursing Associations in Connecticut—The Bureau of Public Health Nursing of the Connecticut State Department of Health has recently made a study of 83 public health nursing associations in Connecticut. The following are some of the data found under the headings of the different services included in the program:

#### 1. Maternity

All associations give some prenatal care. In 5 associations, urinalysis and blood pressure readings are routinely made at the time of the visits. In 4 associations, urinalyses only are done.

#### Delivery Service

48 give this service

- 14 give the service only in emergency  
21 do not give the service at all
2. *Tuberculosis*  
There are only 2 associations in the state which do not include tuberculosis nursing as part of the generalized program. This is explained by the fact that there are special facilities in these towns for the care of such cases.
3. *School*  
Of 93 generalized associations in the state, 50 include school nursing in the program and 43 do not. School nursing is a specialized activity in 38 of these 43 associations, 16 being in large cities and the remaining 22 in towns ranging in population from 1,880 to 18,740.
4. *Hourly Nursing*  
There are 16 associations giving hourly service.
5. *Clinics held (Continuously)*—

- (This information was obtained several months ago and is probably less than the number at the present time.)
8. *Charges made for services:*  
Charges vary from \$.50 to \$1.25.  
6 associations charge \$.50.  
20 charge \$.75.  
\$1.00 is the most common fee asked.
9. *Cost of nursing visit:*  
The cost varies from \$.75 to \$2.80, the high cost indicating fewer nursing visits and more health education activities, social work and clinic services. The average cost is between \$1.00 and \$1.50.—

## EDUCATION AND PUBLICITY\*

WHEN communities come to learn the fact, which is a fact, that a large proportion of the ills of mankind are in their nature preventable, and by due observance of hygienic laws may be prevented; then will the responsibilities of "Boards of Health" be fully appreciated, their acts sustained by public approval, and the fullest practical advantages flow from them.

When the public come to comprehend our true official character, as in time they will, we shall be expected not only to supervise, and, when possible, direct in matters affecting public health, but also to become a source of information in regard to everything connected with the physical well-being of our fellow citizens.—Dr. C. A. Lindsley in his first report as Health Officer in New Haven—a half century ago (1881).

**Education Versus Service**—A comparison of smallpox and diphtheria vaccinations obtained by service of school physicians in the schools of Cleveland, and by education of parents as practised in Detroit, is reported in a brief paper by O. P. Kimball, M.D., Board of Education, Cleveland.

Dr. Kimball concludes that—

As much or more is being accomplished in Detroit than in Cleveland. True, the school physicians themselves are not doing the work, but the parents are having it done. The school physician, nurses and teachers have been teaching health at every school contact to the effect that pupils and parents are gradually accepting the principle that this important business of future health is their responsibility; and because of this, more work is actually being done.

This comparative study was not made with the idea of criticizing the medical work in any school system. It was made solely for the purpose of estimating the results in terms of preventive medicine, of two totally different systems: Health education and medical welfare as school services.

I feel sure that any community will respond to the principles of health education as

Detroit has done. And, what seems very important, the parents and pupils will have the knowledge and experience of taking care of themselves. Also, in so doing they maintain a greater self respect.

The school nurse of the future will be a teacher of health. Instead of dragging a group of children in to have their teeth cleaned and a few extracted she will be teaching them how to keep their teeth clean and how to make use of the facilities which the community offers. Instead of spending twenty minutes scrubbing and cleaning a dirty little face with impetiginous infection, she will do the bigger and better job of taking the child home and teaching mother and child what they should do about this condition.—

*Health Education in Two Cities. Pub. Health Nurs., 450 7th Ave., New York, Nov., 1931. 25 cents.*

**Three Thanksgiving Days**—Dr. John L. Rice presented to New Haven the "makings" of a notable Thanksgiving Day celebration. The November, 1931, issue of *Health*, New Haven Department of Health, was a comparative study of health conditions in that city in 1881, 1931 and 1981. The cover page carried "Thanksgiving" and the

\* Please address questions, samples of printed matter, criticism of anything which appears herein, etc., to Evart G. Routzahn, 130 East 22d St., New York, N. Y.

three dates. A group of mortality figures for 1881 were contrasted with those of 1931—with blank spaces for 1981.

A page of short paragraphs on conditions in 1881 was set off by similar paragraphs concerning 1931. Dr. Howard W. Haggard compares 50 years ago with the present, and Prof. C.-E. A. Winslow pictures 50 years hence.

Plenty of white space. No diagrams or illustrations. Several silhouettes might have enlivened the pages, and would go well with the paper.

A good form of comparative reporting for other city departments—at any time of the year. *Sample free to any health officer.*

**1932 Awards of Merit**—Health materials for publicity, interpretation, or health education, whichever it is or whatever you call it, will be considered by the Awards Committee of the Social Work Publicity Council.

Press stories, photographs, posters, letters, all types of printed matter, mimeographed matter, annual reports, slides, film strips, photographs and descriptions of exhibits or activities, or what?

Send to the editor of "Education and Publicity," to address on the first page of this department every month.

There will be no prizes, but the features of significance will be selected and announced in May, 1932. Send entries now, and more later.

**Digging into the Past**—Elsewhere in this issue is recorded health wisdom dug up by New Haven.

In New Jersey's *Public Health News* is told how "Morristown Citizens Were Given Sound Advice 55 Years Ago" (State Dept. of Health. Sept.-Oct., 1931).

According to a Racine newspaper,

Twenty years ago, the Health Department referred to the press a story about 17 cases of diphtheria occurring in the month of Oc-

tober and added the comment that no epidemic was threatened. At that time, the official population of Racine was 38,000.

The coincidence comes in the fact that the first 10 months of 1931 have witnessed the occurrence of 17 cases of diphtheria in Racine, which is exactly the same number as those reported in 1 month 20 years ago. Moreover, the population is now 68,000, thus making the ratio practically 19 to 1.

Departmental reports and files, and local newspapers in other communities may yield statements, incidents or facts, interesting and stimulating in the present day.

**The Advertiser and the Schools**—The organizations seeking wider educational use of broadcasting are stimulating much discussion of the "sponsored program" in relation to the classroom. One center for this discussion is the National Committee on Education by Radio, 1201 16th St., N. W., Washington, which issues a semi-monthly *Education By Radio*. Copies free. In "Advertising Invades the Schools" (Sept. 10, 1931) is the following taken from the 1931 report of the California Commission for the Study of Educational Problems:

Radio advertising invades schools—It has always been a fundamental principle of American education that the schools must protect their children from exploitation; that no interest shall be permitted directly or indirectly to advertise in the classroom. The commission regrets to report that this principle is being flagrantly violated in many California schools and that the regular work of the children is being interrupted, largely because modern methods of advertising have insinuated themselves into the school system.

By donating to the public schools fine radio and motion picture programs, and cleverly enlisting support therefor from teachers, parents, and school officials, a number of California business firms today are inducing the schools to grant them advertising time in the school-room. The commission is unable to see any practical difference between printing the words "Brown and Company are good merchants" on the blackboard and permitting the words "Brown and Company are making you chil-

dren a present of this fine program" to be spoken repeatedly in the classroom or to be flashed upon a motion picture screen.

The admission into the schoolroom during school hours of radio and film programs carrying "good will" publicity establishes precedents which naturally lead other firms to try to gain admission for their own advertising. Granting one firm such a privilege while denying it to others confers an unfair trade advantage.

An interesting example is a well printed 6-page folder on Foods For Growing Boys and Girls issued by a state tuberculosis association. At the foot of the last page appears "Courtesy of . . .," naming a food manufacturer. Not a line in the text emphasizes the uses of cereals or otherwise promotes that food business. The "food chart" gives less space to cereals than to fruits and vegetables. It does include some of the trade names for cereals. Send 2 cents to Michigan Tuberculosis Association, Lansing, if a copy is desired.

Recently among the free material displayed by one of the most influential health agencies in New York was a folder containing a recommendation disapproved by the great body of health workers.

*What precautions should be taken?*

*What lines should be drawn?*

*What encouragement should be given to commercial interests?*

**Trouble News Invited**—"Troubles," problems, unsolved questions as to the future development of health education—whatever you have on your mind—may well be told to Chairman Galdston or any member of the Section Council. Early in January the usual mid-year meeting of the Council will be held to plan the 1932 program. Suggestions from the floor will be most welcome.

**High Tide at Montreal**—The attendance of those concerned with health education, the nature of the program,

the use made of education and publicity headquarters, and the intensity of interest in the development of health education and the functioning of the Section made a most gratifying combination.

We look forward to an even better time at Washington in 1932.

**Selecting Topics for a Conference or Convention**—An outline on this subject has been prepared for discussion by program committees who wish to study the theory and technic of making up successful programs. The outline is also being used by some program committees as a check against the plans they are making. *Copies free* from editor of this department.

**Convincingly But Not Positively**—F. P. A., in *New York Herald-Tribune*, unconsciously pictures a frequent difficulty of writers on health subjects:

Most of us were told that Mr. William Gillette's 1929 appearances as Sherlock Holmes constituted his farewell tour. And now, the day after Christmas, he will begin a farewell tour. And that, gentlemen, reminds us of the fellow who crashed the No Admittance sign. "Hey, what's the idea? Can't you read?" "Sure, but it don't say 'Positively.'"

The difficult art of being convincing when we cannot be as positive as, say, the patent medicine men!

**The Doctors Do It**—The official health examination campaign of Greater New York physicians is on a sound continuing basis.

The health examination idea is, as every physician knows, nothing peculiarly new. Fifty years ago the subject was proposed to organized medicine through resolutions at medical society meetings. Ten years ago the Committee on Public Health of the Medical Society of the County of Kings discussed the matter and in 1925 examined 91 of the members of the society. In 1926 the committee issued a Report of its experiences and Chapter V of that report was entitled "Records, Equipment and Follow-up." *The Health Examiner* in the present issue reprints this

chapter which reflects the consensus of opinion of the group examined and the examiners.

The above is from *The Medical Examiner*, the 24-page, miniature magazine, issued by The Greater New York Committee on Health Examination, 2 East 103d St., New York. 10 cents; \$1.00 a year.

The committee has issued a new leaflet to be placed on waiting room tables for patients to read and take with them. Cards with the following copy, in script type, have been issued.

In the interest of continued good health you are urged to visit your physician for a health examination at regular intervals.

This measure of preventive medicine and personal health service is endorsed by the Five County Medical Societies of New York and the New York Academy of Medicine.

Engraved cards are supplied at 2 cents each; printed cards and leaflets are free—in Greater New York. *Samples free.*

**Neither Distinction Nor Difference**—Probably the health worker who issued the statement below used the words we have italicized only to emphasize the significance of the exhibit, and did not mean to imply a distinction between "impressing the public mind" and doing an "educational" job.

It is not only for the purpose of *impressing the public mind* with the menace to health of impure air and dirty streets that an exhibit will be held . . . but it is being arranged primarily as an *educational measure* to stress the possibility of preventing this nuisance as well as health hazard.

**Is Mental Hygiene Oversold?**—When the public wants something as badly as it seems to want mental hygiene, it is probably going to get it in some form or other. The task of the organized mental hygiene movement is to look that fact in the face and to deal

with it as best it can," says Stanley P. Davies in "The Public Mind on the Private Mind." This is the sub-title of "Education of the Public on Mental Hygiene," a paper presented before the Educational Publicity Division, National Conference of Social Work.

The paper reviews the comments of psychiatrists and others that mental hygiene has been oversold. They believe that a demand has been created out of all proportion to the extent to which it is possible to deliver the services of properly trained psychiatrists, of psychologists and psychiatric social workers of clinics and other services.

Those who believe that mental hygiene is oversold in this sense fear that the creation of a demand, before proper facilities exist to meet that demand, invites not only the development of misguided, half baked even though well intentioned, ventures in mental hygiene, but also opens a wide field for quacks and charlatans who are only too ready to exploit all possibilities. Such a situation as they see might be compared to the widespread national advertising of a highly desirable commodity, the production of which is, however, so limited that the genuine article is on sale in very few places, and with people elsewhere so convinced, through effective advertising of their great need of that commodity, that they are being sold inferior substitutes or entirely spurious articles.

After reviewing thoughtfully both sides of this program of over selling service Mr. Davies nevertheless comes to the conclusion:

The field of greatest opportunity for educational and publicity work in mental hygiene lies wide open. Mental hygiene, real mental hygiene, has not been oversold. Mental hygiene means not mental disease, but mental health. It is primarily concerned with the normal, not with the abnormal. It is, or should be, positive not negative in its approach.

Just what this positive approach would be is described and illustrated at length in a most helpful way. That editors recognize a need for this thor-

ough analysis of the problem of mental hygiene propaganda is indicated by the number of sources listed below for obtaining the paper.

In *Proceedings of National Conference of Social Work*—1931. University of Chicago Press, 5750 Ellis Ave., Chicago. \$3.00. In *Mental Hygiene*, 450 7th Ave., New York. Jan., 1932. \$1.25. Reprint, 15 cents. In brief form, "What Grown Ups Cry For." *Survey Graphic*, 112 E. 19th St., New York. Dec., 1931. 30 cents.

#### Publicity by the County Nurse—

Several publicity or interpretation items are included in a suggested program of work for the county nurse issued by the Division of Public Health Nursing, New York State Department of Health.

The nurse may expect for her committee immediately upon her arrival (among other items listed): Suitable and sufficient publicity regarding her arrival.

Here is an opportunity for the state department or the state tuberculosis association, whichever is most directly concerned, to serve both the local committee and the new nurse. The local committee may not know what to say in print when the county has a nurse for the first time, or to reexplain the service when a new nurse arrives. And what shall they say about the nurse herself? Does the state health agency supply the local committee copy to be used in the newspapers?

Where the territory covers a county or more than one community the formation of local committees will be very helpful in various ways (among others): To disseminate accurate information in the community regarding the nurse's work in general and regarding the details of new work to be developed.

But does the committee know what to "disseminate," and how? Does the nurse know?

Does the state office send to the com-

mittee or to the nurse copies of good news stories from other communities, as examples? Or offer ready-made stories now and then to be adapted locally? Or tell of reading references that will help in the job of "dissemination"?

Under "Aids in Systematizing Rural Work" are suggestions for zoning the county and making a schedule of visiting periods.

Have this schedule printed or mimeographed for distribution to doctors and supervisors, for posting in appropriate places throughout the district, and for publication in the newspapers.

For the newly trained nurse or even one of some experience, the above simple suggestion immediately raises a row of barriers to be hurdled.

What should be said in introducing and explaining the zone schedule? Does that suggestion call for one or two or three forms of the schedule for the three uses? Just how should a zone or community schedule be put down on paper in a form easy for the nurse, and practicable for use by those who are to use it?

Absurd questions? Then try it out yourself, and then imagine the newly-made county nurse who has had no experience in explaining herself and her job, and has never had mimeographing or printing done, or has never "put anything into the newspaper."

Is there any place for her to write for samples? Will the state department or state association send her a model form or specimens of what other nurses have done?

The county nurse is but one among the health workers who come up sharply against brand new chores in promotion and interpretation. What is being done to help them? What more might be done?

#### MAGAZINE ARTICLES

To be quoted; to be commended; to be questioned—if need be.

"The Airplane Germ Peril." *Literary Digest*. Nov. 4, 1931. Based on *Lancet* article.

"The By-Products of an Accident." *Literary Digest*. Nov. 28, 1931. Based on *National Safety News* article.

"The First Fifty Years," by C. W. Lieb, M.D. *Collier's*. Dec. 12, 1931.

"Don't work too hard!"

"The Frost on the Baby Crop." *Literary Digest*. Nov. 28, 1931. Infant mortality. Based on *Good Health* article.

"Keeping Children Well in Winter," by W. R. Ramsey, M.D. *Farmer's Wife*, St. Paul. Dec., 1931.

"Noisy Ambulances." *Literary Digest*. Nov. 14, 1931. Based on *New York Times* article.

Manuscript for rural readers will be welcome to Health Editor, *Farmer's Wife*, St. Paul.

When you have a specially good press release, or article in your house organ it may get into *Literary Digest* if sent to the editor in New York City.

#### UNEMPLOYMENT

"Writer Warns of Glaring Errors in Articles for Food Pages," by L. H. Milliman. *Editor and Publisher*, Times Bldg., New York. Nov. 28, 1931. 10 cents. Detailed analysis to show "How to Live on Ten Cents a Day Features" often built on imagination and poor arithmetic.

"Emergency Nutrition," by Henry C. Sherman. *Child Health Bulletin*, 450 7th Ave., New York. Nov., 1931. Free. How to spend the food money. Economizing Safely. Leaflet by Connecticut State Dept. of Health, Hartford.

They Proved It: Dairy Products the Basis of an Adequate Economical Diet.

6 pp. National Dairy Council. Free.

The American Social Hygiene Assn., 450 7th Ave., has outlined specific needs in the social hygiene field growing out of depression conditions. Free. Also in *Bulletin*, Massachusetts Society for Social Hygiene, Little Bldg., Boston. Nov., 1931.

"Tuberculosis Is Never Unemployed." *Crusader*, Wisconsin Anti-Tuberculosis Assn., Milwaukee. Dec., 1931. Why tuberculosis work must go on.

"Dairy Products in the Adequate Low-Cost Diet." *Dairy Council Digest*, National Dairy Council, 221 N. LaSalle St., Chicago. Nov., 1931. Free.

"The Second Winter." *Pittsburgh's Health*, Dept. of Public Health. Nov., 1931. Disease usually accompanies extreme depression; worry is dangerous; the emergency must be met.

"Stalwart Citizens" (who are in need), and "They Must Be Helped." *Health*, New Haven Dept. of Health. Oct., 1931. Appeals for Community Chest support.

Principles and policies on administration of relief are outlined by President's Organization on Unemployment Relief, 1734 New York Ave., Washington. Free.

#### NEW

*Better Times*, now published by the Welfare Council, 122 East 22d St., New York, appears in a brand new dress, about 8" by 11" in size. Weekly bulletin issues; 4 magazine issues a year. For those who wish news of health and welfare activities in New York City. Samples free.

*White House Conference Happenings*, Interior Bldg., Washington. Free. Follow-up activities; "scope and status of publications"—past and to come.

The Provincial Dept. of Health, British Columbia, started a *Health Bulletin* in September.

## BOOKS AND REPORTS

**The Great Physician. A Short Life of Sir William Osler—***By Edith Gettings Reid. New York: Oxford University Press, 1931. Price, \$3.50.*

This is the story of a man rather than a physician. We meet the man, but are told about the physician. The book is one long eulogium. In that sense it is extremely discouraging to mere mortals. Had Dr. Osler been permitted the luxury of a single weakness, or had not some of what may have been weaknesses been rationalized into nobilities, the book would be more of an inspiration. In speaking of Dr. Osler's numerous biographical essays the writer remarks:

His essays are not characterizations; they are idealizations of what was best in his subject, of what the man might be, not exactly what he was. . . . You are left with a somewhat exaggerated idea of the virtues of his subject.

Can the author of the present work then be censured for following in this respect the example of one for whom she has such obvious admiration?

Regardless of any one-sidedness it may have, the book makes extremely interesting reading. There is a vividness of presentation which is remarkable, though the degree is not uniform. We meet Dr. Osler at his table; we romp with him in the nursery; we enthuse with him over a rare edition added to the library; we accompany him to the sick room; but, while we may look into his laboratory or his clinic, we do it as through a glass door. We are informed that he is busy. We may even enjoy the courtesy of being informed as to what he is doing, but to get back into personal contact, to renew the bonds

of fellowship, we must wait and rejoin him as he emerges.

This work will doubtless delight the many friends of Dr. Osler in this country and abroad. Few men had the gift of making friends to the extent possessed by him. A vast number of younger men cherish the remembrance of his geniality and aid.

The book is beautifully printed.

MAZÛCK P. RAVENEL

**School Ventilation—Principles and Practices—***Final Contribution of the New York Commission on Ventilation, New York: Bureau of Publications, Teacher's College, Columbia University, 1931. 67 pp. Price, \$1.00.*

The appearance of this "final contribution" presumably marks the end of the reincarnated New York Commission on Ventilation, which engaged in studies of the effects of various types of school ventilation, from 1926 to 1929. This report is certainly not the "final" word on this much discussed and highly controversial subject and as a "contribution," it can be judged only from the standpoint of its value in clearing away certain earlier errors and misconceptions concerning both the principles and the practices of school ventilation.

Both the proponents and the adversaries of the commission will be interested to learn that its members now admit, as a result of the recent studies, that ". . . the general uniformity of results, with varying air flow and with unit ventilation and window inlets, raises serious doubts as to the earlier conclusions obtained (sic) by us in 1923. . . ." In our own earlier work ". . . the superiority of window gravity

*ventilation was based on differences in respiratory illness in attendance obtained by methods which we now know were inadequately safeguarded."* Of equal interest will be the statement that "... slight differences in room temperature, deviating only 2° or 3° above or below 70°, do not exert a measurable influence upon the respiratory disease incidence. This contradicts our own earlier conclusions . . ." (p. 41).

And of the utmost importance is the admission of the fact that "*Our earlier view that window gravity ventilation is definitely superior to plenum ventilation from the standpoint of the liability to respiratory infections must apparently be abandoned . . .*" (p. 48). (Italics T. J. D.)

Furthermore, there is absolutely nothing in the text to justify the implication on the paper jacket of the book, and the definite statement in the newspaper release that announced its publication, that systems of mechanical ventilation are *per se* a menace to the health of the pupils. In fact, on page 41, it is stated that "it makes no difference to the health of the pupils . . . whether this air is provided by a plenum fan, a unit ventilator, or a window inlet" and, on page 66, we are told that "Desirable air conditions may be obtained . . . (a) by plenum ventilation; (b) by local unit ventilation; (c) by window-gravity ventilation," while on page 54, fan ventilation is even recommended "In certain schools where outdoor noise or dust or odors may make it inadvisable to keep the windows open. . . ."

The above statements indicate what scientific investigation actually reveals, namely, that there is nothing inherent in mechanical forms of ventilation inimical to the health of the pupils, and why the commission should, in face of these facts, label it a menace with one breath and approve or recommend it in the next is incomprehensible. It is the

condition of the air in the classroom that is important, not the means by which the condition is obtained or maintained, and it is well-known that debilitating and dangerous overheating may occur with any system of school ventilation that is not intelligently operated.

While the above confessions of error will partially purge the souls of certain members of the commission, they will no doubt cause embarrassment to certain organizations and groups which placed their respective stamps of approval on the earlier conclusions of this august body.

With so much recantation, it will, perhaps be a source of wonder that the members of the commission try still to maintain "that both respiratory-illness-absence and respiratory-illness-inattendance may be used as satisfactory and reliable measures of the health of the pupils . . ." when the absence of objective diagnostic standards for certain respiratory illnesses is so widely deplored, and when, as Greenwood has it, there is certainly no "unambiguous relation" between classroom air conditions and the so-called minor affections of the respiratory tract. The commission is in possession of facts, not published in this book, regarding the inability of various observers—teachers, nurses, and physicians—to agree on diagnoses; facts that do not lend the slightest support to this thesis.

It is also difficult to explain on any ground but bias, why this quasi-medical group, seeing all reasons therefor on the ground of healthfulness shattered, steps out of its rôle and continues to advocate window-gravity ventilation on economic grounds—grounds as uncertain as were the previously advanced (and now admitted—erroneous) ideas of health. It is indeed unfortunate that the whole subject could not have been considered dispassionately and scientifically, free from the influence of preconceived notions that have colored the conclusions.

For the student of the science, as for the practitioner of the art, this little volume, with its ambiguities, inconsistencies and contradictions, will be a wholly inadequate and unsatisfactory guide to the principles and practices of school ventilation.

THOMAS J. DUFFIELD

**Jurisprudence for Nurses**—By *Carl Scheffcl, Ph.B., M.D., LL.B.* New York: Lakeside Publishing Co., 1931. 166 pp. Price, \$2.00.

Every practising nurse is dogged by the law and it behooves her, therefore, to know something about the legal rights and responsibilities of her profession. This practical book supplies the information in a concise and useful form. It deals with such subjects as the legal status of nurses, their legal obligations, their relationship to contracts and wills, and their criminal responsibilities.

Topics such as these are as essential to the education of a nurse as is a knowledge of bacteriology or chemistry. The application of these facts should serve to prevent litigation and promote efficiency in the business and professional relationships of nurses. The book is well printed, has a good index, and contains lesson quizzes at the end of each chapter. It should be indispensable to all practitioners of nursing, especially since it is the only text of its kind.

JAMES A. TOBEY

**Handwashing in Schools**—*Report of a study made by Cleanliness Institute, New York, N. Y.*

The object of this study was to determine the extent to which the 26 million school children in the United States are having a chance to practice handwashing at school. Data were gathered from a representative group of 145 schools (124,088 pupils) of every type, geographically distributed in 15 states scattered throughout the coun-

try, and with widely varying forms of organization. Findings include information regarding the presence of adequate equipment (hot and cold water, soap and drying facilities in sufficient amounts), its location, and the type of school organization (interest of teachers and administrators, provision of time for handwashing under supervision, and care of equipment). In the majority of the schools studied, equipment was found to be inadequate, but in every case more efficient organization would have made its use more effective.

In addition, through the coöperation of 21 manufacturers, and other companies, an intensive study of various types of handwashing in actual use was made in 8 of the schools in Newton, Mass. This investigation demonstrated the practicability of different types of equipment, and gave data on time, water, and soap consumption per 100 handwashings under varying circumstances and in different locations.

Facts and figures are clearly arranged, and the inquiry has materially advanced our knowledge concerning handwashing among the school children of the United States.

RUTH I. PARSONS

**The Conquest of Old Age. Methods to Effect Rejuvenation and to Increase Functional Activity**—By *Peter Schmidt, M.D.* New York: Dutton, 1931. 307 pp. Price, \$5.00.

This book is a defense of the Steinach operation, the author having been a disciple of Steinach.

The first part of the book, devoted to endocrinology, is sound and interesting, and the author gives a number of case histories backed up by photographs "before and after" which almost force conviction. Unfortunately the book is addressed to laymen as well as doctors and we have already had too much evidence that this is a dangerous matter to bring before the public. One point

in which we thoroughly agree with the author is his statement in the preface that he hopes "to do away with the stigma of the ludicrous which has hitherto attached to the physiologist in the laboratory and to the clinician in his daily practice as far as attempts at rejuvenation are concerned."

It is interesting to know that the author committed suicide, in spite of his firm belief in the possibility of rejuvenation. The book is unfortunately marred by attacks on physicians which accuse them of prejudice, obtuseness and self-interest which leads them to distortion of facts and unfairness.

The book can be commended to those who know enough of medicine to judge properly of its worth, but not to the public. The make-up is excellent.

MAZYCK P. RAVENEL

**Kansas City Health and Hospital Survey**—*Prepared by The Committee on Administrative Practice of The American Public Health Association and the Kansas City Public Service Institute. Made under the direction of the Committee on Public Health and Welfare of the Chamber of Commerce of Kansas City, February, 1931. 329 pp. Price, \$2.00.*

Where complex factors are involved, the first step toward betterment is a study of existing conditions. Such a preliminary study is essential where public health is concerned; public health has so many social, industrial, economic, and individual factors that an extensive program of betterment will fail unless those who propose it have prepared the way by finding out what is actually being done, by studying the opportunities for betterment, and by securing in advance the adherence of an interested body of opinion. This procedure seems to have marked the Kansas City Health and Hospital Survey.

In general the survey gives evidence of being carefully made, and it is liber-

ally provided with illustrative figures and charts. It is easy to read because of the literary presentation of its material and the excellent work of the printer.

This journal has an especial interest in certain matters presented. The chapter headings, Maternal and School Hygiene, Public Health Nursing, Industrial Hygiene, and Popular Health Education, suggest possibilities not always fully appreciated and certainly only partially attacked. The Kansas City report does not touch on the possibilities of mental hygiene activities in these fields. It remarks that there is no nursing service for mental hygiene. Special classes for mental defectives are noted. For over a dozen years Kansas City has maintained a psychological laboratory where studies are made on the difficulties of backward children.

More is said about other matters and there is a chapter on mental hygiene. The inadequacy in conception and in administration of the city's provision for the mentally ill is commented on and hope expressed for something better. Apparently little improvement has occurred in these facilities since the Missouri Survey over a decade ago. Where a municipality is negligent in such matters, the influence of the state should inform and correct public opinion about the matter. But the philanthropic and socially minded of Missouri are still struggling with the problem of making the activities of the state anywhere nearly adequate to the needs so that no pressure on municipalities may be expected from that source for many years. Perhaps the colored mental patients are even less well cared for than the white.

It is possible that there will again be in Kansas City a medical school operated and supported by the Commonwealth. If this be so, we hope that the policy of German university cities may be followed, and that the psychopathic hospital may be part of the university

hospital group, under the direction of the professor of psychiatry, operated for the benefit of all persons in the community who fall ill of mental disorders, and at the same time used as a teaching center. Then physicians who go out from the school of medicine will carry an adequate understanding of disorders that affect the mode of behavior and the body of belief of the individual, and a suitable knowledge of how to treat them and where to refer those who need more special care.

Time was when a health survey might not include the field of mental hygiene, but now this topic is sure to receive thoughtful attention. A careful study will in time be followed by appropriate action.

S. W. HAMILTON

**General Bacteriology**—By *Edwin O. Jordan, Ph.D.* (10th ed. rev.) Philadelphia: Saunders, 1931. 819 pp. Price, \$6.00.

This has been a standard text since 1908, when the first edition appeared. It has now reached the tenth edition, and in the meantime has undergone a number of revisions and many reprints, a history which proves that it has won its way on its merits.

The size of the present volume has been increased by some 40 pages. The chief changes are in the sections on variation, undulant fever, the paratyphoid group, the filterable virus diseases, the pathogenic yeasts, and the anaerobes. A number of new and good illustrations have been added.

We cannot but commend the author for his treatment of Nomenclature. He has used "tentatively" some of the newer suggested generic names, although he holds, we believe correctly, that the names of bacteria will continue to be ruled by convenience until a general and rational system can be worked out by international agreement.

It seems supererogatory to commend a volume which has attained such a firm

position in the literature of bacteriology. We can only say that this latest edition upholds the standards set by the first and those which have succeeded each other in the meantime.

The printing and make-up are excellent.

MAZYCK P. RAVENEL

**Industrial Accident Prevention, A Scientific Approach**—By *H. W. Heinrich.* New York: McGraw-Hill, 1931. 366 pp. Price, \$4.00.

This work is one of the publisher's series of insurance manuals and is especially designed for industrial executives and safety engineers.

It is based upon 17 years' experience with the engineering and inspection division of the Travelers Insurance Company and the accident publications which have appeared from time to time from that company are incorporated herewith. It is the author's contention that science may be applied practically and successfully to the prevention of accidents, using the term "science" in the sense of knowledge of principles or facts. The principles laid down have been applied so extensively that they indicate beyond a doubt their practicability and effectiveness.

All the essential principles are discussed in the first chapter, the remaining chapters simply developing various phases of the subject. Method is stressed more than detail, on the theory that, if it be properly selected and applied, satisfactory results must eventually follow. The chief danger at present is in assuming that industry is already well enough acquainted with the principles and now applies them effectively in practice.

The four fundamental principles of accident prevention are executive interest and support, cause-analysis, selection and application of remedy, and executive enforcement of corrective practices. Nearly 100 pages are devoted to guarding—practically all of the 150-odd il-

illustrations falling within this chapter. Eleven appendixes, comprising some 85 pages in smaller type and numerous tables, amplify the text.

The subject matter is comprehensive, well assembled, spiced with numerous case citations and experiences, and constantly emphasizes the necessity for determining the hazards for the given individual rather than general or mass hazards, which seems reasonable. A brief bibliography accompanies. The type, general get-up and printer's art are in keeping with the usual excellency of this well known publishing house.

EMERY R. HAYHURST

**The Community and Social Welfare**  
—By Cecil Clare North. New York: McGraw-Hill, 1931. 359 pp. Price, \$3.50.

Too often our public health programs, particularly when they are planned by state or national executives, ignore the fundamental fact that an effective program must be a community program, designed not only to fit the public health needs of the particular community but also taking cognizance of the other local social problems and machinery.

This study of community organizations is useful to the public health worker not so much for the chapter on a program for health, in which there is little if anything which will be new to him, as it is for its rather complete and attractive presentation of the whole community problem to which the health program must be adjusted.

The discussion of public and private agencies is particularly pertinent to the public health field and the soundness of the viewpoint is indicated in the comment:

The consensus of informed opinion everywhere has been that the system of public health administration is a pernicious one and that the greater progress toward satisfactory public administration will be secured by retaining the expenditure of all pub-

lic funds in the hands of public officials and developing in private agencies the independent position that comes from raising their own funds.

HOMER N. CALVER

**Dietary Suggestions**—By C. D. Christie, M.D., A. J. Beams, M.D., and E. M. Geraghty. Chicago: American Medical Association, 1931. 156 pp.

Books on dietetics have generally been prepared either for the more or less normal person or for the individual who is hospitalized. This one differs from most others in that it is intended for the "vertical patient." It discusses diets suitable for constipation, gastric disturbances, and diabetes, and also high caloric, low protein and reducing diets. In each instance there are offered many practical recipes which the physician may prescribe for the ambulant patient in need of such diets.

All of the valuable material now conveniently assembled in this well printed little book appeared during 1930 in the *Journal of the American Medical Association*, and *Hygeia*. Dr. Beams collaborates with Miss Geraghty in 5 of the 7 chapters, while Dr. Christie is credited as co-author of the section on diabetes only. As Dr. Morris Fishbein states in a brief introduction, this useful book should meet with a wide and favorable reception.

JAMES A. TOBEY

**Abstract of Literature on the Production, Processing and Distribution of Fresh Milk. Vol. I.** Chicago: International Association of Milk Dealers, 1931.

We have received from the Executive Secretary of the International Association of Milk Dealers the above mentioned volume of abstracts. The work has been done under the sponsorship of the Committee on Laboratory Methods of the association.

The abstracts cover the literature in practically all fields and departments of the fresh milk industry, including production, processing, quality control, and

distribution. For each the name of the original author and its source of publication are given.

The work has been well done and doubtless will furnish to milk producers much material which will aid them and be of benefit in improving the quality of the supply. MAZÏCK P. RAVENEL

**The History of Paediatrics—the Progress of the Study of Diseases of Children up to the End of the XVIII Century—***By George Frederick Still, M.D. (Cantab.), Hon. LL.D. (Edin.), F.R.C.P. (London).* New York: Oxford University Press, 1931. 526 pp. Price, \$8.00.

Dr. Still has upheld the reputation of the scholarly Englishmen in his choice of diction and careful selection of historical material with which he traces the evolution of pediatric thought from the 4th century before Christ to the end of the 18th century. This absorbing volume supplements and extends the excellent biographical and historical material already published by Caulfield, Garrison, Ruhrah, Sudhoff, and Foote.

It is a delight to be guided through the mazes of thought concerning childhood diseases by one who has so thoroughly sifted and so logically arranged his material. While they are presented in chronological order, the biographical sketches are interwoven to present a continuous story. First of all, one turns naturally to the early history of infant feeding, the difficulties encountered, and the solutions offered. The earliest de-

scriptions of diphtheria and rickets will bear careful reading today. The chapter on the first children's dispensary in England is replete with personal incidents in the life of George Armstrong, its founder. That "George Armstrong deserves an important niche, not only in the history of paediatrics, but in the history of social welfare" is convincingly shown.

The volume is made more interesting by the facsimile reproductions of the title pages of a number of the classics in medicine. Full page portraits of the pioneers in pediatrics add much to the volume. RICHARD A. BOLT

**Some Biting Remarks—***By Happy Goldsmith.* New York: Barnes, 1931. 43 pp. Price, \$.75.

Merely to announce that Clifford Goldsmith has written a book should send the throngs to the book store to get a copy immediately. In both the text and the sketches Professor Happy is here at his best. From its stunningly brilliant cover to its last hilarious line it is stimulating entertainment for old and young.

This is a book to inspire the health educator; it is first aid for the teacher and the parent; and, for the week-end guest who must take a gift to the children, it's like finding your carfare.

The reviewer's principal advice to the reader is not to start on this book when he is hungry because if he does he will run right out to luncheon and order spinach. HOMER N. CALVER

# A SELECTED PUBLIC HEALTH BIBLIOGRAPHY WITH ANNOTATIONS

**Mental Hygiene Publicity**—Has an eager public been oversold on mental hygiene? The answer seems to be "no," not on the right kind of educational material, of which more is needed to counteract the efforts of charlatans, faddists, and well-meaning but misguided reformers.

DAVIES, S. P. What Grown-Ups Cry For. *Survey Graphic*, 20, 3: 253 (Dec.), 1931.

**The American Family**—What restricted immigration, divorce, birth control, urbanization, industrialism, and other social factors are doing to American statistics. Population is increasing, the sex ratio is becoming equalized, the size of the family is decreasing but there are more families. An excellent and stimulating paper.

DITMER, C. G. Uncle Sam's Family. *Survey Graphic*, 20, 3: 249 (Dec.), 1931.

**Fish**—"Among the many food faddists that have existed, there has not yet been a fish fad." The author thereupon does what he can to make up for the deficiency by featuring fish for fighters, fish for children—whole families, in fact.

GETTEN, D. H. The Place of Fish in the Dietary of Adults and Children. *J. State Med.*, 39, 11: 656 (Nov.), 1931.

**Epidemic Meningitis Movements**—The general epidemiologic characteristics of meningitis are studied. The evidence indicates a surprisingly large proportion of the population infected during epidemics. The highly variable inter-epidemic interval is from 6 to 12 years.

HEBER, A. W. The Movements of Epidemic Meningitis, 1915-1930. *Pub. Health Rep.*, 46, 46: 2769 (Nov. 13), 1931.

**Voluntary Euthanasia**—This elo-

quent plea for the legalization of voluntary euthanasia (easy death) for victims of hopeless, painful conditions was the presidential address delivered at a recent meeting of British Medical Officers of Health.

MILLARD, C. K. The Legalisation of Voluntary Euthanasia. *Pub. Health*, 45, 2: 39 (Nov.), 1931.

**Kentucky Maternal and Child Health Project**—How the county health unit has developed its maternal and infant hygiene activities is interestingly set forth in the description of two county projects.

PRATHER, H. E., and GRATT, E. R. A County Health Department Program for Maternal and Child Health. *South. M. J.*, 24, 11: 963 (Nov.), 1931.

**Physical Educational Trends**—An excellent statement of the shift in emphasis from physical training to health education, of interest to health workers generally.

ROGERS, J. E. Trends in Physical Education. *J. Health & Phys. Ed.*, 2, 8: 19 (Oct.), 1931.

**Research in Nutrition**—"We should not look for quick results from improvement in human nutrition . . . the benefit of better feeding usually becomes fully apparent only when continued throughout a large part of the life cycle and often the benefit is greater to the second generation than the first." These observations are a part of a most interestingly presented discussion of some of the vitamins.

SHERMAN, H. C. Some Recent Advances in the Chemistry of Nutrition. *J. A. M. A.*, 97, 20: 1425 (Nov. 14), 1931.

**School Children's Teeth**—Among the many most important findings of this study of more than 12,000 oral

examinations is this startling one: 90 per cent of children in each age group had one tooth or more decayed, missing or filled.

STOUGHTON, A. L., *et al.* Dental Decay and Corrections Among School Children of Different Ages. Pub. Health Rep., 46, 44: 2608 (Oct. 30), 1931.

**What Is Health Consciousness?**  
—Is it an introspective, emotional concern with one's "innards" or a deep concern in applying the present knowledge of health promotion and disease control for the benefit of all? There is plenty of opportunity for speculation in the answer.

SUNDWALL, J. Are We Becoming Overly Health Conscious? J. Health & Phys. Ed., 2, 8: 9 (Oct.), 1931.

**Diphtheria Immunity and Tonsillectomy**—Schick and Fopper reported a noticeable reduction in Schick test reactors among tonsillectomized children (see Bibliography of Jan., 1930). This finding was not confirmed in a Baltimore study of school children and adults, as no significant difference was discerned between those operated upon and those still enjoying their tonsils, whether in a normal or pathologic condition.

WHEELER, R. E., *et al.* Antitoxic Immunity to Diphtheria in Relation to Tonsillectomy Am. J. Hyg., 14, 11: 555 (Nov.), 1931.

## BOOKS RECEIVED

THE MENTAL DEFECTIVE. By Richard J. Berry and R. G. Gordon. New York: McGraw-Hill, 1931. 225 pp. Price, \$2.50.

THE SCIENTIFIC BASIS OF SOCIAL WORK. A Study in Family Case Work. By Maurice J. Karpf. New York: Columbia University Press, 1931. 442 pp. Price, \$3.75.

# NEWS FROM THE FIELD

## POLIO MYELITIS—MULTIPLE CASES IN A FAMILY

Our present conception of the epidemiology of poliomyelitis was well set forth by Aycock in a recent number of the *Weekly Bulletin*. During the course of the present outbreak of poliomyelitis in this city we have kept a record of the number of instances in which two or more cases have occurred in a single family. The results of the inquiry fit in with Aycock's idea that, while the virus of poliomyelitis is widespread, infection going on to paralysis is rare. Were it otherwise we should expect to see multiple cases of the disease in a considerable proportion of the families where the infection has appeared.

From January 1 to October 3 nearly 4,000 cases of poliomyelitis were reported to the Department of Health. The number of families in which more than 1 case occurred was only 111.

These multiple cases are still being analyzed, for it is important to determine in how many instances it seems probable that infection was spread from one patient to the other, and how many probably represented an infection from the same source. The distribution of the multiple cases was as follows:

MULTIPLE CASES OF POLIO MYELITIS IN NEW YORK CITY, JANUARY 1 TO OCTOBER 3, 1931

	Families with 2 cases	Families with 3 cases	Total cases
Manhattan ..	15	0	690
Bronx .....	10	0	546
Brooklyn .....	66	1	1,951
Queens .....	9	1	587
Richmond ...	8	1	151
City .....	103	3	3,925

—*Weekly Bull.*, City of New York Department of Health.

## WESTERN BRANCH MEETING IN DENVER

THE Third Annual Meeting of the Western Branch, American Public Health Association, will be held in Denver, June 2, 3, and 4, 1932. The meeting will adjourn on Saturday, June 4, to the meeting of the National Tuberculosis Association in Colorado Springs, only 60 miles away, which occupies the following week. Eastern representatives to the meeting will include Dr. Louis I. Dublin, Dr. E. L. Bishop, Dr. John A. Ferrell, and Dr. Kendall Emerson.

## SCHOLARSHIP IN HEALTH EDUCATION

A FULL tuition scholarship of \$500 is available in the field of health education at Massachusetts Institute of Technology (Department of Biology and Public Health) for 1932-1933, to cover the full scholastic year from September to June. This scholarship will be awarded to a candidate recommended by the National Tuberculosis Association, the award to be made in June, 1932. Applications should be received not later than May 15, and those interested are invited to write to the Child Health Education Service of the National Tuberculosis Association, 450 Seventh Avenue, New York, N. Y.

## INDUSTRY'S YOUNG WOMEN MOST FREQUENTLY INJURED

THE largest numbers of industrial accidents to New York women for any age group during the years ending June 30, 1929 and 1930, were found to occur among girls 18 and 19, according to a special bulletin of the New York State Department of Labor. Out of a total of 8,091 injuries to women during the first year, 473 were to women

18, and 399 to women 19 years of age. The year following, 591 and 529 respectively were found in the 18 and 19 year groups.

#### LESLIE DANA GOLD MEDAL

THE Leslie Dana Gold Medal, awarded annually for "outstanding achievements in the prevention of blindness and the conservation of vision," was presented to Edward M. Van Cleve, of New York, Principal of the New York Institute for the Education of the Blind. Mr. Van Cleve was selected for this honor by the National Society for the Prevention of Blindness in coöperation with the St. Louis Society for the Blind through which the medal is offered by Leslie Dana.

The Leslie Dana Medal was awarded last year to Dr. George E. de Schweinitz, of Philadelphia, former President of the American Medical Association, of the American Ophthalmological Society, and the College of Physicians of Philadelphia. In 1929 the Medal was awarded to the late Dr. Ernest Fuchs, of Vienna, Austria, who was recognized in his profession for a number of years before his death as "the world's greatest ophthalmologist."

#### ROVING WITH THE MIGRANTS

SOCIAL centers among migrant families working in fruit and vegetable canneries and on truck farms and ranches in the Chesapeake area, southern New Jersey, Colorado, and the Pacific Coast, are being conducted in connection with a study of migratory labor by the Council of Women for Home Missions, in which 15 Protestant denominations coöperate. The service given in these centers, as described in a book entitled "Roving with the Migrants," includes day nurseries, first aid, instruction in cooking and nursing, and supervised play.—U. S. Children's Bureau, Washington, D. C.

#### HOSPITAL SCHOOL IN LISBON

MANUAL work, singing, and drawing, in addition to ordinary elementary school subjects, are being taught to patients 3 to 10 years of age in a hospital in Lisbon, Portugal. This work was established through the efforts of one of the physicians. It is staffed by two trained teachers, and though maintained by private contributions it is officially recognized as a public school. Motion pictures and other entertainments help to interest and amuse the children.—U. S. Children's Bureau, Washington, D. C.

#### AFTER-CARE FOR INFANTILE PARALYSIS VICTIMS

NEW York City hospitals caring for infantile paralysis patients have been requested to report the discharge of such patients to the Children's Welfare Federation of New York, which has undertaken to see that they have proper after-care. Nursing organizations in each borough have agreed to give treatments under the direction of a physician, and, when necessary, to connect patients with orthopedic clinics and to provide braces and transportation. Cases not registered with the federation will be followed up by health department nurses. This plan has been adopted with the approval of the hospitals and the city commissioners of health, according to an announcement in the *Journal of the American Medical Association*.—U. S. Children's Bureau, Washington, D. C.

#### DELAWARE'S SCHOOL DENTAL PROGRAM

DELAWARE has this year instituted for its public schools a dental program which requires that all children in the first six grades shall be examined by a dental hygienist. The present first-grade children are to be reëxamined at their completion of the third grade and the sixth, the results of the care received

being recorded. The actual work on the children's teeth is to be done by private dentists selected by the parents, and on completion of the work the dentists are requested to sign the cards on which the hygienists indicated the repairs needed.—U. S. Children's Bureau, Washington, D. C.

## PERSONALS

ELLENORE VON ELTZ has become publicity secretary of American Nurses' Association, New York, N. Y.

DR. WILLIAM W. BAUER of Racine, Wis., F. A. P. H. A., has been appointed assistant secretary of the Bureau of Health and Public Instruction, to succeed Dr. Rosco G. Leland, who was elected to the secretaryship of the Bureau of Economics at the February meeting of the American Medical Association Board of Trustees. Dr. Bauer will take up his new duties about the first of the year.

BRIGADIER-GENERAL M. A. DELANEY, U. S. Army, F.A.P.H.A., was recently promoted from Colonel, Medical Corps, by President Hoover. He returned recently from Manila, P. I., where he was Medical Adviser in Public Health and Sanitation to Governors General Henry L. Stimson and Dwight F. Davis. He was formerly White House physician to President Taft.

DON M. GEISWOLD, M.D., DR.P.H., F.A.P.H.A., has been provisionally appointed consulting epidemiologist on the staff of the Division of Communicable Diseases, State Department of Health, Albany, N. Y.

ADMIRAL CAPY T. GRAYSON, M.D., an alumnus of the Medical College of Virginia, Richmond, delivered its founder's day address on December 1, to mark the 94th session of the institution. His subject was "The Modern Trend of Medicine."

## DEATHS

DR. ROLAND H. STUBBS, former Health Officer of Waterford, N. Y., Member A. P. H. A., died recently in the Leonard Hospital, Troy, N. Y., at the age of 77. He was one of the original staff of the hospital, and was a medical examiner for the New York Life Insurance Company for 35 years.

MAJOR-GENERAL SIR DAVID BRUCE, British medical officer, died recently at the age of 76, on the day of the funeral of his wife. He was best known for his researches on tropical diseases, sleeping sickness and Mediterranean fever, and in 1924 was president of the British Association for the Advancement of Science.

## CONFERENCES

January 12-16, Pure Air and Clean Streets Exhibit, New York Academy of Medicine, New York, N. Y.

January 22-23, American Social Hygiene Association, New York, N. Y.

January 25-29, Second Heating and Ventilating Exposition, Cleveland, O.

April 4-8, American College of Physicians, San Francisco, Calif.

April 11-15, American Nurses Association, San Antonio, Tex.

April 11-15, National Organization of Public Health Nursing, San Antonio, Tex.

April 11-15, National League of Nursing Education, San Antonio, Tex.

May 10-15, Annual Congress of The Royal Institute of Public Health, Belfast, Ireland.

June 2-4, Third Annual Meeting, Western Branch, American Public Health Association, Denver, Colo.

June 6-9, National Tuberculosis Association, Colorado Springs, Colo.

July, The Second International Conference of Social Work, Frankfurt, Germany.

### Dental Policies in a Public Health Program\*

ALFRED WALKER, D. D. S., F. A. C. D.

*Chairman Advisory Committee, Murry and Leonie Guggenheim Dental Clinic; the Community Dental Service; New York Tuberculosis and Health Association, New York, N. Y.*

AS I see the implications in the title, this paper should cover the following points: (1) the question as to whether dental care is of real concern in a public health program and why; (2) what type or types of dental programs are to be advocated for inclusion in a public health program, including a consideration of the proportionate attention which the teeth should have in the program; (3) the technic which should be followed in the dental program or programs.

First, we are to consider whether the care of the teeth is a proper part of a public health program. It is rather generally agreed that disease of the teeth and adjoining structures is detrimental to the general health. Statements to this effect are made and accepted practically without question,<sup>1</sup> yet I venture to say that the views of the average health officer on this point are rather vague. As a matter of fact, perusal of dental and medical literature reveals the fact that, while much attention is being given to individual cases where such relationship is suspected, no worthwhile statistical studies are on record tending to show the effect of dental disease on the health of a community. I believe that one of the early studies needed in this field is a survey along the lines just indicated.

Another point in this connection to be noted is that by far the largest number of cases of focal infection reported deal with adults or

---

\* Read before the Child Hygiene Section of the American Public Health Association at the Sixtieth Annual Meeting at Montreal, Canada, September 15, 1931.

those beyond school age. We seem not to have applied the lessons so learned to the school child, especially from the preventive aspect. Sufficient cases are on record, however, to indicate that acute rheumatic fever, heart trouble, chorea, kidney disease, and other ailments, frequently occur in childhood and have a definite focal infection as background. Care of the teeth is quite as important in the effort to prevent or treat these diseases as is attention to the tonsils.

The cutting down in efficiency of mastication when teeth are diseased is a point to be considered. Its influence is so obvious that it need only be mentioned.

Another aspect of dental disease which requires consideration is the effect of such disease both directly and indirectly on earning power. Indirectly, the loss of teeth results in disfigurement which may frequently have an unfavorable influence on the ability to secure employment. The psychological effect on the individual may also have an adverse effect on earning power. More directly, dental disease through its influence on health may result in enforced idleness, economic loss here being accentuated by the cost of medical treatment. This aspect of dental disease should be made the object of careful statistical study, which would of course involve the consideration of the dental as well as health condition, and would, therefore, call for assistance from both the dental and medical professions. I have no hesitation in stating, however, even without the backing of such a study, that dental disease is a serious menace to the health of the entire population from childhood on, and will, therefore, continue the discussion as though this statement were universally accepted. The conclusion may then logically be drawn that teeth occupy a major place in a public health program.

Dental policies in a public health program naturally center on the child. There has been too much of an assumption in the past, based on convenience, that this question could be confined in its application to the *school* child. The trend of all recent researches in this field of dental care indicates that to begin with the school child is to start very nearly too late. Inconvenient though it may be, we must accept at the outset the dogma that an efficient dental program must have as its starting point an age well below that at which the child enters school. Let us not assume, however, as has been done by more than one student of this problem, that good dental care in the early years of life will eliminate the need for dental care later on. Even good teeth have been known to suffer from disease under unfavorable influences to which they may readily be exposed during the years when the child is in school. We may as well recognize at the outset that there is no

panacea for dental ills; no immunizing vaccine which once administered will afford lasting protection. In other words, if a dental program is adopted and put into effect, it should be one which there is reasonable expectation of maintaining over a considerable period of time. It might be embarrassing to be in the position of the man who caught hold of the tail of the bear and found that he could not let go.

When we come to recommend a dental policy to administrators of public health programs, we find ourselves confronted with the need for making a selection from one of several quite dissimilar programs which have been advocated by various members of the dental profession. This is a cause of some embarrassment to our profession, since it indicates rather clearly to those outside of it that the ideal program has not yet been discovered. It means that we must decide on such theories as all dentists can agree on, and present these with the entire weight of united dental opinion behind them. As it happens, those things on which all the members of our profession can agree are also the most economical procedures to employ in a broad public health program.

We find it possible to classify these procedures under

I. Education

II. Examination of individual mouths and limited dental treatment for a young age group

III. The continuance of the second plan into the higher age groups with a more extensive treatment program

It will be understood that the educational program specified under I would also be included in II and III. Because of the fact that dental treatment for children has certain aspects which set it off from the rest of dental practice, so that it is even considered a specialty by some, there arises also the question as to whether (a) the community dental program for the child should be universally applied, or (b) be confined to indigents. If (b) is accepted it is then to be decided whether the educational part of the program should be spread over the non-indigent as well as the indigent group.

It may be the simplest avenue of approach to consider the points just raised in the inverse order of presentation. We will accordingly discuss the educational phase of the dental program in so far as this is given in and through the schools. It is obvious that it will cover all economic levels as far as they are represented in the school population. It requires no further effort or greater expense to reach the non-indigent group with the educational efforts that are put forth. If the

educational program is to be carried to the preschool child and the expectant mother, as it is only logical that it should, it would seem wise to make a distinction between the indigent and the non-indigent groups. However, experience has indicated that the prosperous members of the community do not acquire dental knowledge along with their greater income; nor is their interest in the teeth of their children and desire to have dental defects cared for proportionately greater than among the indigent. If dental disease is a community problem, as I believe it to be, the dental educational program should have universal coverage.

With regard to points (a) and (b), my previous remarks indicate that the requirements of indigent children will be so heavy as to eliminate the question of providing community dental service for the non-indigent, except as a purely academic question. Dental care for the indigent is both an individual and a community problem. Whether it can justify itself on purely economic grounds as a means of avoiding general illness and disability and the economic losses entailed thereby, can be determined only by a fair and thorough trial. Such a trial would be of tremendous value even though the answer to the question proposed might be in the negative.

Coming now to programs I, II, and III, I may well summarize I by quoting from the Iowa Plan for Dental Health Education.

The objective of dental health education is to bring about a universal observance of the fundamental principles of preventive dentistry, to the end that we might have healthier, happier and more efficient men and women.

The Iowa "Plan No. I without mouth inspection" is the one which is advocated by its proponents, and is thus described:

The experience of the Bureau (of Dental Hygiene, University of Iowa) in the State of Iowa has indicated that there is but a slight relationship between a school dental inspection and a successful dental program. . . .

The success of any health program is directly dependent upon the ability of the teachers and nurses, especially the former, to interest the children.

The plan therefore urges the child to visit the family dentist for the mouth inspection, which method is undoubtedly more educational in its effect than a hurried examination made in the school room by a dentist.

The immediate objectives to be sought after (are)

1. To get all children to eat foods that build good teeth
2. To get all mouths in each (school) room free from decayed, abscessed and stained teeth
3. To get all children to have their own toothbrushes and to brush their teeth at least once each day

This is a program which is designed to give information and arouse interest, and should result in the greatest number of those financially able seeking dental services for their children. It is to be remembered that under this even examination of the teeth is excluded by preference, on the assumption that this as well as dental treatment is the function of the dentist in private practice or clinic. This should be regarded as the minimum dental plan. Its benefits are undoubted and its results in time will unquestionably justify the money required for its administration.

Plan II is based on the supposition that educational efforts alone will not prevent a very large amount of dental disease, which will therefore become a community charge just as is disease of more serious proportions. To treat dental disease, when it has occurred, naturally necessitates its detection. Therefore the minimum program of dental treatment consists of careful examination of the teeth at intervals of 6 months, with charting of any caries or gingival disease which may be discovered. This should be supplemented by what is commonly called cleaning the teeth or, as the dentist usually phrases it, prophylactic treatment, included with which there is to be a definite educational message and careful instruction in the use of the toothbrush.

The prophylactic treatment usually given by the dental hygienist has been attacked in recent years as being less than its name implies. In other words, it is stated that the cleaning of the teeth by the dentist or dental hygienist does not prevent decay. If we stop the prophylactic treatment with simple cleansing of the teeth, we may agree that this claim is largely true; but the prophylactic treatment is, in the first place, an object lesson in the care of the mouth, and if it is accompanied by an educational talk designed to stimulate the interest of the patient in keeping his teeth clean by daily brushing, as it should, it then becomes a potent weapon of defense against disease. It is for this reason that I specify that the prophylactic treatment must include adequate demonstration of toothbrush technic. Another justification of the cleansing of the teeth by the dental hygienist is that the educational message can be most effectively delivered while the patient is in the chair. If for no other reason, this might well justify the time spent in this operation.

Plan II, as just outlined, is one which requires no complicated equipment. The salaries of dental hygienists are less than those of dentists of corresponding experience and ability. While suitable rooms and facilities must be provided, a considerable part of the equipment may be of a portable type thus cutting down the investment and

making it possible to cover a considerable territory with a limited number of operators.

Plan II by its nature is relatively most effective with the younger age groups. As children get older, those who cannot afford dental care develop caries to a certain extent in spite of the educational and prophylactic efforts, and the time of the dental hygienist is therefore less productive of positive benefit. This program should, therefore, be limited to children below 6 years of age, with special effort to reach the preschool child.

Plan III includes the features of plans I and II, and adds the filling of cavities, extraction of such teeth as require it, and treatment of inflamed gums. The protective operations known as prophylactic odontotomy, if done at all, would fall under III. There still remains considerable misunderstanding about this particular protective measure, and it should be undertaken only by those who fully comprehend its application. Plan III should cover the older age groups as far as is financially possible. This requires the services of dentists and a more expensive and less mobile equipment. In this connection, however, it should be noted that in some communities much success has been attained through the use of a travelling dental clinic set up in a large bus. The principal expense, of course, is for dentists' salaries, supervision and supplies, and it is also to be borne in mind that the community which undertakes to treat teeth for its indigent children has assumed a responsibility which it cannot lightly put aside after a short period.

I call attention to the fact that sponsors of dental treatment programs have often taken the stand that they would limit the children so treated to a narrow age range, one corresponding roughly to the kindergarten and the first grade. There has been a possibly unconscious assumption that, if cavities occurring at the age of 6 or 7 were filled, Divine Providence would take care of any that formed subsequently if the child could not afford to pay for dental service. The lack of logic in such a program should be obvious.

To extend the age for dental treatment is not so expensive as it might at first seem, inasmuch as mouths under constant supervision do not as a rule develop large cavities. To start a program of fillings at a sufficiently early age, especially in conjunction with educational and prophylactic effort, is to cut the cost of such treatment per child to a very reasonable figure. Such a program cannot be made to reach as many children as the more limited age program, but at least the work which is done is not lost in a short time, and remains a permanent asset. I do not presume to set the upper age limit for this program, but believe that in fairness to the child it should coincide approximately with the age at which wages may be earned.

It would be unfair to close this paper without some comment on the subject of diet, of which so much is heard today. I do not decry the attention which vitamins are receiving, but believe that the angle of approach should be that of the general health, rather than a specific effort to influence tooth structure. I look upon dental disease not as a local condition, but as indicative of a shortcoming somewhere in the body. In other words, if we have perfect health, we should have perfect teeth. On the other hand, I think of diet, as something that the physician should prescribe, something distinctly in his domain. I would like furthermore to record by belief that the problem of dental disease will not be solved by the dietary route alone, but that this is simply one agency, quite as important an agency being mouth hygiene, i.e., the care of the mouth by the patient, the dental hygienist and the dentist.

---

## Spain

THE new Constitution of Spain, unlike that of the Spanish Monarchy, contains clauses on child welfare. For instance, it specifies that the family is to be under the special protection of the State. Parents are required to feed their children, to care for them, and to give them an education. The State is to watch over the enforcement of this law and to provide financial aid to needy parents. Parents have the same duties to their children of illegitimate birth as to those born in wedlock. The State also assumes the duty of protecting mothers and children and accepts the principles of the Children's Charter of Geneva.

The Constitution makes primary instruction free and compulsory. The State is ordered to enact legislation for the purpose of enabling all citizens of small means to obtain any education they desire.

*Other Child Welfare Measures by the New Government*—A recent decree provides for the organization of a Division of Child Hygiene in the Bureau of Public Health. The division will also do prenatal work and work for the prevention of maternal mortality.

Another decree orders the establishment of school lunch rooms throughout Spain to be managed by the local school authorities under the supervision of the State. The funds will be supplied jointly by the State and the municipalities; private donations will also be accepted. The decree points out the importance of establishing as many such lunch rooms as possible and of reaching the greatest possible number of children.

The municipal Government of Valencia has decided to reserve a certain park in that city exclusively as a playground for children on certain hours a day in order to remove them from the streets of the city and the accompanying danger. The children will be under the supervision of public school teachers.—*Pro Infantia*, Madrid, 1931, No. 185.

# Practicability of Epidemiological Methods in the Control of Syphilis\*

WILLIAM L. MUNSON, M. D., F. A. P. H. A.

*District State Health Officer, Granville, N. Y.*

THE problem of the control and eradication of syphilis seems to me to be one of the easiest ones we have in public health, providing we approach the problem with the attitude of mind and with methods similar to those used in the control of other communicable diseases.

I do not want to be misunderstood as to the value of education in any phase of public health work—I am a great believer in it—but so far as syphilis is concerned, I think that our publicity and education have far outrun and overrun our attempts at the practice of hard-boiled epidemiological methods of control of the disease. As an example, to be perfectly frank, I cannot see the value of special talks to school children on gonorrhea and syphilis and what is to be accomplished. I believe in proper sex education but it seems to me that this can well be done by the teachers and parents themselves.

The control of syphilis, as I see it, is predicated upon three very definite and distinct factors; as it were, it rests upon a tripod supported by three legs:

1. Reasonably early and accurate diagnosis
2. Early and proper treatment
3. Sole leather epidemiology

Early diagnosis which is accurate is the keystone of the control of any communicable disease. You must know what you are to control before you know how to control it, and you must get started with that control before the thing is spread all over creation.

There is an increasing tendency, I fear, among public health folk to minimize the value of good clinical medicine. I feel that perhaps some of the newer men going into public health are missing this altogether. Just recently I caught the beginning of a small sized smallpox epidemic by recognizing an atypical case of smallpox. This diag-

---

\* Read at a Joint Session of the Health Officers and Epidemiological Sections of the American Public Health Association at the Sixtieth Annual Meeting at Montreal, Canada, September 17, 1931.

nosis was confirmed by the distinguished chairman of the section on epidemiology.\* This early recognition of an atypical case permitted us to get 3,000 people vaccinated almost before some of the typical cases which were contacts began to come down.

Regarding the second standard of the tripod, the question of adequate treatment seems to me quite well taken care of. So far as my experience is concerned I have never seen any lack of facilities for the treatment of syphilis. Adequate treatment is certainly available in New York State.

The question of sole leather epidemiology is the one about which I wish to speak. Apparently from statistics we are really not gaining much headway in the eradication of syphilis. It occurs to me that our failure to control this disease is quite definitely due to the fact that the cases are not properly investigated along practical epidemiological lines.

May I preface some narratives which I wish to give you by stating what may be my feeling concerning epidemiologists and epidemiology?

An epidemiologist is that creature who curiously combines a reasonable scepticism and insatiable curiosity with a passion for the truth and has the ability to recognize the truth when it looks him in the face, and with all this has the initiative to apply sufficient sole leather to the job to get the facts.

The object of epidemiology is to know enough about the behavior of a given disease and a given disease situation to control it. While it may be fun to exercise the mind playing with speculative and hypothetical epidemiology, this pleasurable exercise must be subservient for the most part to the practical. I take it that the taxpayers want us to get as much joy as possible out of our work but that probably that wish is secondary in their minds to putting down outbreaks of communicable disease and particularly in controlling these outbreaks so that their own communities are free from these diseases.

Having viewed for some time the passing scene in public health I have come to a fairly well settled feeling that epidemiologists are made by God and that the man-made type are worth in the market just what they will bring as good clerks.

The true epidemiologist or medical detective, when he has the scent, is perhaps the most stubborn being that you can imagine. He ariseth in the chill of morning and he toileth away into the night.

If we are going to control syphilis we must go to work instead of talking about it. Going to work on syphilis means the same as it does with typhoid fever—epidemiology. Each case must be worked up.

---

\* Dr. Edward S. Godfrey, Director Division Communicable Diseases, New York State Department of Health.

If every case of syphilis were investigated and proper attention paid to the contacts as is done in other diseases, it would not be very long before medical students would have difficulty in obtaining clinical material enough for instruction in this disease.

The trouble with the whole business is that we have not made a real attempt to eradicate the disease. We have played around a good deal with it but sometimes one is forced to wonder just how seriously we have made war. We have probably talked more about syphilis without action than about any other disease in the reportable list.

In doing the epidemiology of this disease, one must be bold, determined, and unafraid. What constitutes good epidemiology in syphilis? I certainly would not be bold enough nor have the temerity to suggest that the following narrative reports may be such but I offer them as something which may point the way to the direction in which we should go.

Apparently syphilis is susceptible to very accurate tracing. The epidemiology for the most part is no more difficult and involved than smallpox. I presume that the difficulty has been with us in that we have, when investigating the disease, failed to speak out boldly with our questions and to proceed with our investigations with the same diligence that we would in typhoid. The reason for this, I believe, is obvious—we are too delicate.

Let me relate some investigations:

#### EPISODE 1

The first intimation which the New York State Department of Health had of anything being wrong in this community was when a Sunday school teacher came to the Director of the Division of Social Hygiene and stated that the wife of a certain official in her community was "dosing my boys with a bad disease." This information was passed on to me, the feeling, I think, being that it was based upon some sexual complex of the complainant.

One day when going through this town I stopped and talked to the Sunday school teacher and became convinced of the honesty of her suspicions and also of their validity. As a result of this interview I made an investigation which uncovered more than even the complainant had suspected. The Wassermanns for the community were checked up. There were a large number, 17 positives, all under fictitious names, but almost all of them taken by one particular doctor.

This doctor was called upon and with some of the information which I had in hand I convinced him that I knew quite a bit about the situation. He then became a fountain of information concerning the cases.

The first lead was to the station agent of the community. The story of this rather prosaic man was interesting and a little pathetic. He had been infected with syphilis by the wife of the official. The station agent was one of two men then "keeping company" with a school teacher; this teacher became infected from

the station agent and then married the other man. The teacher passed this acquired syphilis on to her innocent husband, who, when I saw him, had not the slightest idea that he had syphilis although he had a mouthful of mucous patches at the time. The teacher became pregnant and miscarried a syphilitic fetus. She was outside of the hometown in another community teaching when her secondary lesions developed. The diagnosis was German measles and she was kept under isolation until the first physician in her hometown, who had all the other cases, made the correct diagnosis.

The information which I received from the doctor concerning the names of the persons affected and who had the positive Wassermanns disclosed upon investigation that their infection was unquestionably the same source, that of the wife of the public official.

It was found that this woman was unquestionably about as promiscuous as it was humanly possible to be. My own opinion is that she was probably a nymphomaniac.

There were many sidelights of interest from the viewpoint of human psychology, such as the unquestionable, but perhaps difficult to prove, fact that this woman took her 15 year old daughter as a companion on some of her escapades; also the attempt of the husband to compel his wife to cease her immoral actions even to the point of horse-whipping her.

The woman and her husband, the latter now suffering complete necrosis of his nasal bones, had failed to continue treatment. This I ascertained by investigation with a physician in a nearby city who I suspected might be their attending physician.

It became my duty to go to this official, tell him the whole story which I had found out, and which he denied like a gentleman, meanwhile asking me to talk with his wife. I declined to do this but did state to the husband that he and his wife must get under treatment and stay under treatment and that she must cease passing syphilis about the community and if I found a fresh case of syphilis coming from her I would forthwith proceed to make complaint before the county judge and would have her locked up.

The result was that we got all of the contacts under treatment; the man and his wife went back to their attending physician; and now after quite a lapse of time I have heard no more of syphilis in this community.

## EPISODE 2

In this community several positive Wassermanns were being reported. These occurred among persons who were working for a certain concern. In investigating any disease there are two sources of great information: one is the postmaster, and the other is the station agent. The latter was interviewed in this connection and I asked him where the boys were getting into trouble. He knew the answer, and told me the name of the woman, under pledge of great confidence. I sought this person out and found her with syphilis. A Wassermann was taken which was four-plus. Eleven cases were traced to this person. It was apparent to the health officer and myself that she would be very difficult to handle, and so without any further gestures we appeared against her in court, where evidence was submitted of her activities and infection, and the judge upon the evidence presented committed her to Pavilion G of the Albany Hospital until such time as she would no longer be a danger to the public health. Some time has elapsed since the circumstances de-

tailed here and no more syphilis has been traced to the woman in question or known in the community.

### EPISODE 3

Two young girls came to the doctor in a vacation area and consulted him about their "cold sores" which could not be cured. The doctor was a very knowing and canny one and became suspicious promptly that the "cold sores" were the primary chancres of syphilis. Both girls were virgins. Here is the story:

Inquiry showed that these girls had both been kissed by the chauffeur of a family summering in the community.

Our investigation of the chauffeur showed him with a mouthful of mucous patches. He at first stated he would not say where he acquired his infection. One does not need to be too gentle in these investigations. Inquiry finally placed the source of the infection as a certain woman in town, who was then investigated. She was very indignant and vehemently inclined to resent the intrusion into her private affairs. Her denials and protestations of innocence were so intense and great that I thought she needed more investigation. She was found to have a positive Wassermann and was then given the choice of telling me or telling the judge the men who might probably be infected from her. She finally became convinced that her best interest lay in telling the truth. Two other men were found infected with syphilis. All of the persons, except herself, were cared for by private doctors; she was sent to a clinic in a nearby city, where she was treated. No further cases were ever traced to her.

### EPISODE 4

Just as collateral information might I tell the following? Some years ago a mother inquired why her two girls, 7 and 9 respectively, had to "go to the toilet so often." I responded that they might have some infection and she inquired what, to which I replied, "gonorrhea." The mother abused me profoundly and at length. However, a little later she produced the two children at my office. Both had a positive gonorrheal smear and were virgins. I advised the woman, who was the wife of a farmer who employed three hired men on his farm, to have her husband examine these men. The husband proved to be a weak-kneed fellow and would not follow this request, so the mother herself made the examinations and found one man with a discharge which proved to be gonorrhea.

This fellow was a recent emigrant from Ireland where he said the story was believed that "if a man with the disease could touch parts with a virgin, the disease would disappear into the air." The judge who heard the case gave him 40 years.

### EPISODE 5

The following investigation was made by Dr. John A. Conway, a confrere and brother District State Health Officer in the New York State Department of Health. Thirteen cases of anal chancre were reported in college boys. It was only after several weeks of questioning that the source of infection was found. After a good deal of hammering one boy eventually admitted relations with a young colored chef employed at the dormitory of one of the colleges. This chef, by the time the information was obtained, had departed for parts unknown.

The matter was then reported to the District Attorney, who secured an indictment, the chef being found and apprehended cooking at a boys summer camp. He

was arrested and sentenced to Elmira Reformatory for an indefinite period and later transferred to Matteawan Prison where he is still confined. This colored boy, 23 years old, was always neat and well dressed. He was popular with the boys at the university, and he was the only colored person in the village.

In but one instance did he give any money and that was to a farmer boy who delivered vegetables to the college, the amount being \$.25 each time. It might be noted that this boy was the only one of those infected who might be classed as sub-normal mentally, the others being normal college students.

Just as a sidelight to this report might be presented the fact that a minister was present at the trial who was interested in the colored boy and could not be convinced of his dangerous criminal tendencies and that his condition was mentally abnormal. This well meaning cleric declared that if they would liberate the boy in his custody he would be responsible for his good behavior.

Persistent questioning—almost third degree, if you will—finally after 2 months of effort produced the truth.

#### EPISODE 6

A married man consulted me for a discharge which showed gonococci. He insisted that it could not be a specific infection, but of course I had the actual proof and it could not be disputed. He then told me this story. He and his wife had for a long time been promiscuous, but due to the fact that the children were growing up they decided that it was a poor family policy and so had pledged themselves to the abandonment of extra-marital relations. But he claimed his wife had not kept faith.

A few nights after that the wife consulted me. She had a positive smear; she was told that she had a specific infection; and then she stated to me the same story exactly that the husband had given me, with the remark, "The men are all alike—you cannot believe them on their oath."

Both parties seemed to me to be so utterly honest in their denunciation of the other and there was something in their stories which appealed to me as being the truth that I persisted with my inquiries. On one occasion, while questioning the woman, I said to her, "When were you last pregnant?" This made her obviously a little uneasy. I could see that she flinched and did not care to answer. The questions further persisted in this direction discovered the fact that about 3 weeks before that she had been supposedly a couple of months pregnant and had gone to an abortionist whose name she gave and I believe as a result was infected with gonorrhea. I knew the methods of operation and technic used by the man who did the job. He used a probe which passed from one client to another without sterilization.

#### EPISODE 7

The fact of venereal disease being carried from place to place and starting up little local outbreaks is in my opinion the means of keeping up the rate. The following relation of facts unquestionably has been duplicated many, many times.

An Uncle Tom's Cabin company came to a community about which I know and played a one night's stand. The result of this was 1 case of syphilis and 3 cases of chancroid. These were personal patients of mine. The case of syphilis was in a married man and the disease was passed on to his wife without her knowledge. She never consulted me but I have understood that she was under treatment

for syphilis without her knowledge of what she had. This man acquired his disease from the person who portrayed little Eva.

In addition, to my personal knowledge, there were 4 other cases of chancroids and all of these men had acquired their disease from a colored woman in the show.

These 4 cases occurred in my practice when I was one of six practitioners in the community. It is fair to assume that there were many other cases as a result of Uncle Tom's one night stand in the community. If the cases had been promptly reported and epidemiology done on each no one knows how much suffering and how much disease would have been prevented.

The outstanding element which contributed to the solution of the problems here narrated is determination, with a dash of boldness. Public health is in spots becoming so diplomatic and so tactful that one becomes a little suspicious. Perhaps we must forget some of our polish and get a little push into the business.

Rural syphilis, I believe, for the most part is a series of local outbreaks, such as I have described.

There is just one conclusion: Every case of syphilis should have a hard-boiled, determined, and bold epidemiological investigation.

---

## The Lady of Godey's: Sara Josepha Hale

THE life of Sara J. Hale, who has been dubbed "The Lady of Godey's," is the subject of a book recently published by Lippincott, and reviewed at length in the *New York Times Book Review* for November 22, 1931. The magazine carrying the name of Godey was known to everyone who read at all, but this biography has reminded us of matters which had certainly escaped the memory of almost everyone. It shows that Sara Hale was a pioneer in many matters for which the professors of hygiene and public health workers now take credit, and which are usually considered very modern. Articles on physical culture and child hygiene, as well as those on housekeeping, home making, architecture, gardening, cookery, etc., appeared 60 to 75 years ago, due to the farsightedness of "The Lady of Godey's." About 1850 the magazine had attained an unprecedented circulation of 150,000 copies, and there can be as little doubt of its influence in regard to health matters as there is in regard to the general subjects which it covered, including, as it did, an amazing number of reforms and innovations, such as the adoption of Thanksgiving as a national holiday, women as teachers in the public schools, women medical missionaries, Seaman's Aid Society, day nurseries, and public playgrounds.

While we give all honor to this pioneer, let us thank the author, Ruth E. Finley, for her painstaking study, which has brought to light the health facts which had apparently been forgotten by the few living who knew them, and are new to the present generation.

# Syphilis from the Epidemiologist's Point of View\*

THOMAS PARRAN, JR., M. D., F. A. P. H. A.

*New York State Commissioner of Health, Albany, N. Y.*

THAT much is unknown about the epidemiology of syphilis is apparent even to the casual student of the disease; yet syphilis seems to excite the interest of few epidemiologists here or abroad. The extension of knowledge in the epidemiology of the disease and the better application of existing knowledge are the next steps most needed in control.

Although the origin of syphilis is clouded in obscurity, there is no disease around the history of which there has been raised such a storm of controversy. Because syphilis spread throughout Europe in the last years of the 15th century and the first years of the 16th, many students have concluded that it was imported by the sailors of Columbus on their return from their voyage of discovery. The disease, however, was described before 1492 in Europe and in the ancient writings of the Chinese and Japanese reference is made to a disease which undoubtedly was syphilis. The weight of evidence discredits the American origin of syphilis, although it is certain that about the end of the 15th century this disease spread rapidly over the whole of Europe. In many instances it took on the character of an ordinary communicable disease. The reason for this widespread prevalence has been discussed at length by Hirsch,<sup>1</sup> who summarizes the evidence which leads him to conclude that syphilis existed prior to the return of Columbus's sailors from their voyage of discovery. Sudhoff<sup>2</sup> and Garrison<sup>3</sup> also have reached the same conclusion after exhaustive investigations.

## THE CAUSATIVE ORGANISM

To say that the causative agent of syphilis is unknown appears to be rank heresy, so generally is the *Treponema pallidum* accepted as the inciting agent, although Koch's postulates have never been fulfilled as regards this disease.

---

\* Read at a Joint Session of the Health Officers and Epidemiology Sections of the American Public Health Association at the Sixtieth Annual Meeting at Montreal, Canada, September 17, 1931.

*Cultivation*—The *T. pallidum*, in my opinion, has never been grown on an artificial medium outside of the human body, in spite of thousands of attempts by the most competent bacteriologists in the world.<sup>2</sup> A few reports of success in the cultivation of organisms, which on sub-culture prove invariably to be non-virulent, probably represent accidental contaminating saprophytic spirochetes. The evidence is far from conclusive that the *T. pallidum* is the sole etiologic agent. Questions which remain unanswered concerning the cause of syphilis are:

1. Is the *T. pallidum* alone the causative agent? if so, is the visible spiral form but one stage in the life cycle? or
2. Is there an "x-factor," the presence of which is necessary as a symbiont with *T. pallidum*? or
3. Is the true causative agent unknown, and the *T. pallidum* a saprophytic concomitant of the true cause?

Certain it is that during the period of incubation of the infection in rabbits one may search diligently through innumerable microscopic fields and fail to find a single organism; yet the inoculum will produce the disease.

*Life Cycle*—A number of investigators have reported a life cycle, during which the organism passes through an ultra-microscopic stage, and during recent years Levaditi<sup>3</sup> has revived this idea and has described various developmental forms. Warthin<sup>4</sup> also leaned toward this view.

*Physical Characteristics*—The organism is fragile; it does not resist drying; there is no reservoir of infection so far as is known outside of the human body. It is very susceptible to heat, to soap and to chemicals.

*Strains*—Much discussion has arisen as to whether or not there are special strains of the *T. pallidum*. In the case of other organisms differences in strains are demonstrable, and *a priori* it seems logical to assume that they exist in this organism.<sup>5</sup> Evidence which is suggestive but not conclusive has been accumulated indicating that there are special neurotrophic and dermatrophic strains and that the higher rate of involvement of the nervous system among some peoples is a result of infection with a neurotrophic strain.

#### RELATION OF YAWS AND SYPHILIS

It is uncertain whether or not the disease called "yaws," prevalent in the tropics, is a modified form of syphilis. The weight of experimental results points to a difference in the two diseases, while Butler<sup>6</sup>

has presented suggestive epidemiological evidence of their identity. It is still unsettled whether or not an infection with "yaws" prevents the development of syphilitic infection. The only direct experiments in humans are those of Jahnel and Lange,<sup>7</sup> who failed by inoculation to infect two general paretics with a yaws virus although one normal subject took the disease.

#### RESISTANCE TO INFECTION

*Natural Resistance*—There appears to be no natural resistance to an initial infection with syphilis, although Coutts,<sup>8</sup> after citing the virulence of syphilis when introduced into a virgin soil, has suggested the possibility of widespread sub-clinical infection with an attenuated virus, which partially immunizes a large proportion of the population and results in a comparatively mild form of the disease. Also if Warthin's<sup>9</sup> findings which showed the *T. pallidum* in tissues of from 35 to 50 per cent of the autopsies at the University of Michigan Hospital are accepted, our present conceptions of syphilis must be changed. On this basis, infection with the *T. pallidum* must be considered a widespread condition in which only the occasional case comes above the horizon of clinical and serological recognition.

The unbroken skin presents a barrier to the passage of the *T. pallidum* but the mucous membrane apparently does not. Susceptibility to infection appears to be universal except in persons already infected. Once the disease has established itself in the body, its course may vary greatly. Constitutional factors as yet unknown seem to determine the severity of the infection and the susceptibility of the central nervous and cardiovascular systems to involvement. Differences in type of the disease are shown by some races. The dark skinned races are more resistant to involvement of the nervous system, while the negro is more susceptible to cardiovascular disease of syphilitic origin.<sup>10</sup> Sex is an important factor in the course of the disease as well as in its prevalence.<sup>10, 11</sup> Pregnancy seems to exert a specific beneficial effect in promoting latency.

*Acquired Immunity*—Second attacks in themselves are no different from initial attacks. It is well known that second infections with syphilis are of rare occurrence, and as criterions by which infection is judged become more severe, the number of proven cases is reduced almost to the vanishing point.<sup>12</sup>

Following Neisser's<sup>13</sup> work it was thought that this resistance to a second infection was due to persistence of the first, and that susceptibility reappeared when the first infection was eradicated. In recent years, however, Chesney<sup>14</sup> has shown that immunity to a second in-

fection is not dependent upon persistence of the first, but rather upon the length of time elapsing between onset and sterilization. In experimental animals he finds that a certain degree of resistance to re-infection is acquired if the initial infection is allowed to run its course for a few months before the animal is sterilized. This immunity to re-infection is complete to a homologous strain of the *T. pallidum* but is partial only to a heterologous strain. Immunity does not develop if treatment is started early in the course of the disease. The infection in the rabbit can be cured either in the early or the late stage. Animals cured of an initial infection may show different degrees of immunity depending upon many factors, including the length of time the disease was allowed to run its course.

This resistance may be:

1. *Complete* to any subsequent re-infections
2. *Partial*, with the result that subsequent inoculations do not produce any local lesions at the point of inoculation, yet the virus spreads throughout the body and produces a generalized infection
3. *Absent*, the animal being susceptible to re-infection following the first attack of the disease, the second running the same course as the initial one

This partial immunity has a striking significance in regard to the epidemiology of syphilis.

The immunity which develops during the course of syphilis apparently is not a humoral immunity. Antibodies have not been demonstrated. It seems to be a cellular immunity which may be sufficient to prevent any subsequent infection, or to prevent the development of a lesion at the point of entrance, but not sufficient to protect against dissemination of the virus in the body. The whole subject of immunity in syphilis has been reviewed in recent years by Chesney," Harrison," and Brown."

If these degrees of immunity develop similarly in the human, it is likely that many of the cases in which signs of the disease reappear after the lapse of years may be second infections with no local lesions. In other words, the patient who is treated thoroughly and reexamined for years with negative findings, but who ultimately develops signs of cardiovascular syphilis or other late symptoms, may indeed have been cured of his first infection but have been re-infected without an initial lesion. Because of the known tendency of the disease to become latent, syphilologists have established rigid criterions of cure. Are these too severe, and are many cases being overtreated because a second "blind" infection is mistaken for reactivation of latency?

The immunity which develops in the course of syphilis apparently

is interrupted by early arsphenamine treatment. In fact, Bruck in Norway always advocated a policy of "masterful inaction" in the treatment of syphilis, maintaining that all anti-syphilitic remedies depressed the natural immune processes. Recently Bruusgaard<sup>18</sup> has attempted to follow up the patients treated by his teacher Bruck. The results, while not conclusive, indicate that the percentage of general paresis and cardiovascular syphilis is no higher than among patients better treated.

Public health considerations, however, make it impossible to follow such a policy generally. Moreover, if treatment can be started in the sero-negative primary stage, the chance of cure is nearly 100 per cent (Harrison,<sup>19</sup> Moore<sup>20</sup>).

*Onset and Duration of Infectiveness*—Though the onset of syphilis characteristically is with an initial lesion and a secondary rash, no history of these symptoms can be obtained in a considerable proportion of males and in a large proportion of females. Infection may occur with no recognizable initial lesions. There are no criterions by which cure can be determined, and the patient may show late effects of the infection after the lapse of years during which all signs of the disease are absent.

Characteristically tending to latency, the syphilologist is puzzled in many late cases as to whether he should upset the symbiotic relationship existing between the organism and the invaded tissues by vigorous treatment which may in itself impair vital organs; or whether by "masterful inaction" he should risk an infectious relapse with the consequent public health danger, and the development of late lesions as a result of inadequate treatment.

Infectious by sex contact and to some extent by casual contact when open lesions are present, some recent studies tend to confirm clinical observations that the seminal fluid of syphilitics may be infectious for years with no macroscopic open lesions on the skin or mucous membranes.

*Chronic Carriers*—It is uncertain whether syphilis is a curable disease in the sense that every organism can be eradicated from the body with no possibility of relapse.

In syphilis it is well known that a considerable percentage of cases have a tendency to relapse and develop infectious lesions. A comprehensive study of cutaneous and mucosal relapse by Stokes<sup>21</sup> and a collaborating group among 5,952 cases of early syphilis revealed 360 cases which relapsed after original lesions were healed. If in the most expert hands 6.5 per cent of cases relapse, the number in the average clinic and in general practice must be much larger. A committee of

experts assembled by the League of Nations in 1928 outlined as the next most needed step to secure added knowledge of syphilis a study of the results of treatment in various countries.<sup>27</sup>

The most pressing problem in the therapy of syphilis is: Can syphilis in fact be cured? and if so under what conditions? Do our best attempts consist merely in creating a symbiotic relationship between the organism and the tissues, causing no obvious symptoms in a majority of cases but potentially capable of reactivation and infectiousness?

#### PREVALENCE

It is probably easier to exterminate syphilis in a population than to determine its exact prevalence and distribution. Here is a disease in which the time of onset frequently is obscure; the infection often does not rise above the horizon of clinical recognition; a positive Wassermann test may be the only sign of its existence; even a negative Wassermann is no assurance that the infection has been eradicated; and there is no accurately demonstrable end-point.

Statistics as to the absolute amount of syphilis in a population always will be inaccurate, due to:

1. The unknown percentage of cases which are never diagnosed or treated
2. The frequent absence of definite signs of onset
3. The impossibility of determining whether or not the disease has terminated in a given case
4. The reticence of patients and physicians in notification of cases

One can discuss minimum rates, however, in terms of the number of cases constantly under treatment and the attack rate of treated cases. From these rates, plus a knowledge of the age distribution of the population and the age of onset of syphilis, one can determine specific attack rates by age groups and can estimate the percentage of the population which at some previous time has experienced an attack of the disease.

*Cases of Syphilis Constantly under Treatment*—During the past 5 years studies made by, and in coöperation with, the U. S. Public Health Service<sup>28</sup> by the 1-day census method in a population totaling 25,822,137, and typical of the population of the country as a whole, reveal 110,039 cases of syphilis constantly under treatment. This represents a prevalence rate of 4.26 per 1,000 inhabitants, and means that more than a half million people in the United States are constantly under treatment because of syphilis. Rates for certain of the areas are given in Table I.

TABLE I

RATES PER 1,000 POPULATION OF CASES OF SYPHILIS UNDER TREATMENT IN CERTAIN  
LOCALITIES SURVEYED IN THE UNITED STATES CLASSIFIED  
BY STAGE OF THE DISEASE\*

LOCALITY	Total		Early		Late	
	Cases	Rate	Cases	Rate	Cases	Rate
Tennessee (34 counties)	6,323	4.42	2,438	1.70	3,885	2.72
Oregon	2,104	2.40	609	.69	1,495	1.70
Detroit	8,574	6.22	2,898	2.10	5,676	4.12
Mississippi (16 counties)	2,225	3.99	959	1.72	1,266	2.27
Cleveland	6,935	6.03	2,581	2.24	4,354	3.78
Virginia (18 counties)	4,753	3.97	1,775	1.48	2,978	2.48
Iowa	2,990	1.23	1,244	.51	1,746	.72
City of St. Louis and 5 counties	8,293	6.44	2,386	1.85	5,907	4.59
New York State (excl. N. Y. C.)	14,476	2.63	4,139	.75	10,337	1.88
Philadelphia	9,082	4.40	2,702	1.31	6,380	3.09
New York City	29,423	4.90	7,064	1.18	22,359	3.72
14 Communities	4,115	6.71	1,428	2.31	2,727	4.40
Total	99,333	4.05	30,223	1.23	69,110	2.82
Philadelphia, Pa.	9,082	4.4	2,702	1.3	6,380	3.1
Baltimore, Md.	7,462	9.3	1,393	1.7	6,069	7.5
New Orleans, La.	2,676	5.8	1,036	2.3	1,640	3.6
Charleston, W. Va.	1,024	17.0	(a)	(a)	(a)	(a)

\* Data from U. S. Public Health Service Records.

a. Data by stage of infection were not available for the Charleston City Clinic, which reported 45 per cent of all the cases.

The rates vary from 17.0 in one city of 60,000 to less than one per 1,000 in certain rural areas.

*Annual Attack Rate*—Estimates may be made of the annual attack rate from the number of cases found under treatment by the 1-day census and the known turnover of clinic patients. More accurate information is had from a census of new cases which are diagnosed for the first time during a 1-month period. This is available for up-state New York, for 4 large cities, and for 14 additional communities in 6 states, and is presented in Table II.

If the single months during which the census was taken are typical, then there is an indicated annual attack rate of 7.3; divided into early and late syphilis the indicated rate is 3.4 and 3.9 per 1,000, respectively.

If it is assumed that all of the "late" cases, in spite of the physicians' statements to the contrary, had been registered for treatment elsewhere prior to the census, the attack rate of cases which acquired their infection within the preceding year and came for treatment promptly certainly represents a minimum.

TABLE II

ANNUAL ATTACK RATES FOR SYPHILIS ACCORDING TO STAGE OF DISEASE AT TIME OF DIAGNOSIS FOR VARIOUS COMMUNITIES

Name of Community	Population	Estimated Cases * and Annual Attack Rates					
		Total Cases	Rate	Early Syphilis Cases	Rate	Late Syphilis Cases	Rate
Philadelphia, Pa.	2,064,200	19,344	9.4	7,980	3.9	11,364	5.5
Baltimore, Md.	804,874	8,560	10.6	3,972	4.9	4,588	5.7
New Orleans, La.	458,762	6,528	14.2	3,744	8.2	2,784	6.0
Charleston, W. Va.	60,411	2,964	49.1	1,440	23.8	1,524	25.3
14 Communities (Resurvey)	654,581	8,604	13.1	5,592	8.5	3,012	4.6
Upstate New York (Resurvey)	5,786,389	25,524	4.4	10,752	1.8	14,772	2.6
Total	9,829,217	71,524	7.3	33,480	3.4	38,044	3.9

\* Based on cases seeking treatment for first time during a 1-month period.

For every 100 cases constantly under treatment in these communities there were 173 new cases which were diagnosed for the first time during the preceding year, of which 83 were early cases. Applying to the whole country this same ratio to the surveyed cases under treatment in the population of 26,000,000, it is estimated that in the United States 871,000 cases of syphilis are diagnosed for the first time each year and that of these cases 408,000 are early syphilis.

*The length of time patients are treated* is indicated by these ratios,

TABLE III

CASES OF SYPHILIS CONSTANTLY UNDER TREATMENT AND RATES PER 1,000 POPULATION FOR CITIES IN DIFFERENT POPULATION GROUPS

GROUPS OF CITIES	Population	Cases	Rates per 1,000 Population
13 cities over 100,000 (a)	13,699,514	80,734	5.89
7 cities 50,000 to 100,000 (a)	464,929	3,292	7.08
8 cities 10,000 to 50,000 (a)	217,897	2,869	13.16
Total (a)	14,382,324	86,895	6.04
6 cities over 100,000 (b)	1,472,443	7,064	4.80
6 cities 50,000 to 100,000 (b)	435,493	1,753	4.03
56 places 10,000 to 50,000 (b)	1,065,535	3,374	3.17
Total (b)	2,973,471	12,191	4.10

a. Data from U. S. Public Health Service Records.

b. Data from survey of upstate New York, May 1, 1910.

from which it appears that on the average syphilis patients remain under treatment  $6\frac{1}{2}$  months.

*Urban vs. Rural Rates*—The rates of cases under treatment by communities of different population groups are summarized in Table III. In one group of 13 cities, surveyed by the U. S. Public Health Service, of over 100,000 the rate varies from 4 to 13.3 with an average of 5.89 per 1,000; in 7 cities of 50,000 to 100,000 the rate varies from 1.1 to 12.0 with an average of 7.08; in 8 cities of under 50,000 the rate varies from 5.7 to 31.2 with an average of 13.16.

A study of the rates for cities of different sizes in up-state New York where the population is rather uniform and where other influencing conditions are practically the same for all the communities is shown also in Table III. The attack rate in a general way varies with the size of the city, the larger the city the higher the attack rate. However, it should be pointed out that whereas the rate varies with the size of the community when grouped as above, a detailed study of cities shows no direct correlation between attack rate and density of population. The cities studied by the U. S. Public Health Service were widely scattered and the proportion of colored and white population probably was unequal in the three groups. This and other variables probably account for the wide variation in the individual groups.

#### STAGE OF THE DISEASE

Of more significance than the total rate are the rates of early cases in which the infection was acquired within 1 year from the date of survey. Early cases under treatment constitute 30 per cent of the total (Table IV). The considerable variation found in the percentage of early and total cases in different communities may be due to a

TABLE IV

PREVALENCE OF SYPHILIS BY STAGE OF THE DISEASE AND SEX OF THE PATIENT IN COMMUNITIES SURVEYED, SHOWING THE RATES PER 1,000 POPULATION

Syphilis						
Stage of the Disease	Number of Cases *			Rates per 1,000 Pop.		
	Total	Male	Female	Total	Male	Female
Early	32,954	22,155	10,799	1.28	1.70	0.84
Late	77,085	45,710	31,375	2.98	3.51	2.46
Total	110,039	67,865	42,174	4.26	5.21	3.30

\* Exclusive of the Charleston City Clinic cases for which data by Stage of Infection were not available.

declining attack rate; a variation in the delay in seeking treatment; or differences in the effort to keep cases under treatment.

#### TREATMENT

*Time Treatment is Started*—From other sources<sup>21</sup> exact data are available as to the interval between the onset of the disease and the beginning of treatment. Among those patients who seek treatment during the first year, only 11 per cent (204 in 1,734 cases) begin their treatment in the sero-negative primary stage or during the first few weeks when possibility of eradicating the disease is greatest. Another 22 per cent seek treatment for the first time during the primary stage but after the blood Wassermann has become positive, while the remainder, two-thirds of the total, have fully developed secondary lesions before seeking medical care. Expressed in terms of the time which elapses between onset and treatment: one-third of the cases come during the first month; 55 per cent during the first two months; and 37 per cent allow from 2 to 12 months to elapse.

These data deal only with early syphilis and do not include the very considerable number of patients who are diagnosed for the first time during routine examinations, or who seek relief for symptoms years after the onset of the disease. For New York State more than one-half of the males and two-thirds of the females come under treatment for the first time more than 1 year after onset of the disease (both sexes 57.9 per cent). In 18 other communities, including several large cities, less than one-half of the cases coming initially for treatment were classed as "early" syphilis.

Syphilis can never be controlled while more than one-half of the cases are not recognized for more than a year after onset.

*Where Patients are being Treated*—Of the cases in the population of 26,000,000, surveyed by the U. S. Public Health Service, 64 per cent are being treated by private practitioners as private patients, while 36 per cent are being treated in public clinics, hospitals and similar institutions. Forty-one per cent of all of the registered physicians in these areas were constantly treating one or more cases (3,089 physicians in a total of 7,530). The bulk of cases, however, are concentrated in the public clinics and in the hands of very few physicians: 10 per cent of the physicians are treating two-thirds, 5 per cent of the physicians are treating 50 per cent, and 1 per cent of the physicians are treating 25 per cent of the cases. In other words, nearly three-fourths (72 per cent) of all known cases are under treatment by public clinics and specialists; viz., the 5 per cent of physicians who have 12 or more patients constantly under their care.

TABLE V

AGE AT ONSET OF SYPHILIS AMONG 2,227 PATIENTS TREATED IN THE 3 ST. LOUIS CLINICS AND  
IN THE 5 CLINICS PARTICIPATING IN INQUIRY INTO SYPHILIS TREATMENT\*

\* Data from U. S. Public Health Service Records.

## DISTRIBUTION

*Age Distribution*—Haustein<sup>21</sup> has assembled all available data on age at onset of syphilis for various European countries.

Most of the data on age distribution of cases in the United States deal with the age of patients when the case is reported or at the time treatment is started. A tabulation of the age at onset of 2,227 patients with acquired syphilis, selected from among the clientele of seven large clinics in different states, is shown in Table V.

The peak for the whole group occurs at the age of 21; also for both sexes. However, when divided according to color, the peak for colored females is found at 16 years and for white females at 21 years; for colored males at 20 years and for white males 21 years.

An examination of the percentage infected at the two age periods of 20 and 30 years shows very strikingly that females are infected at a much earlier age than males, and that colored persons are infected earlier than white people (Table VI).

TABLE VI  
PERCENTAGE OF TOTAL CASES WHICH OCCUR BEFORE AGE 21 AND AGE 31

AGE GROUPS	Male		Female	
	White	Colored	White	Colored
Age 1-20	21.9	31.6	39.3	47.6
Age 1-30	76.0	84.0	83.7	90.9

*Sex Distribution*—From the prevalence surveys, complete data are available as to the sex distribution of patients. Of the 110,039 patients, 67,865 were male and 42,174 were female, the disease being roughly 50 per cent more prevalent among males (Table IV). Some of this difference may be due to the larger proportion of female patients in whom the disease is not recognized and treated. In support of this is the fact that males under treatment in the early stages outnumber females more than 2 to 1.

The ratio of female to male cases for different countries, collected by Harrison<sup>22</sup> shows a similar preponderance of male infections.

The prevalence of syphilis among pregnant women is of considerable practical interest because of the splendid results of treatment in insuring healthy offspring. Elsewhere<sup>23</sup> I have summarized all available published reports on this problem which showed an average of 6.5 per cent pregnant women infected with syphilis. These reports were chiefly of maternity hospital and dispensary patients.

*Geographical Distribution*—Syphilis is not evenly distributed in the population, although climate itself apparently is not a factor. The distribution between urban and rural areas is presented elsewhere. More prevalent in the southern states than in the northern and western, even though the increase among negroes is eliminated; almost pandemic in boom towns, with a large floating population; comparatively rare in the more static rural populations of some states, more prevalent among those in the lowest economic groups; it is possible to localize somewhat the problem of syphilis.

*Racial Prevalence*—The prevalence surveys reveal a great disparity between negro and white rates, which is supported by many other sources of information. Among a population of nearly 6,000,000 in which negroes form a considerable percentage of the total, the rate of cases under treatment for white was 4.16 and for negro 10.04, per 1,000 (Table VII). Wassermann surveys of whole negro populations conducted in recent years by the U. S. Public Health Service<sup>21</sup> in a number of representative rural counties in southern states, furnish added evidence of the higher prevalence, averaging about 20 per cent of positive Wassermann reactions in the entire negro population.

TABLE VII

PREVALENCE OF SYPHILIS BY SEX AND COLOR OF THE PATIENT IN ONLY THOSE LOCALITIES WHERE THE SURVEY WAS MADE AS TO COLOR \*

SYPHILIS	Total			White			Colored		
	Total	Male	Female	Total	Male	Female	Total	Male	Female
Number of Cases	32,756	19,763	12,993	17,987	11,838	6,149	14,769	7,925	6,844
Rates per 1,000 Population	5.65	6.77	4.51	4.16	5.42	2.87	10.04	10.80	9.28

\* Includes Tennessee, Mississippi, Virginia, St. Louis and 5 counties, Charlestown, W. Va., Baltimore, Md., and New Orleans, La.

*Cyclic Prevalence*—No evidence has been adduced in the United States that syphilis shows a cyclic prevalence comparable with other infectious diseases, except for increases which have followed wars and social changes. In Sweden, a 7-year cycle has been described.

Season seems to have no bearing on the attack rate, although new cases in some clinics increase after the summer and Christmas vacation periods.

## SOCIAL FACTORS

The amount of extra-marital sex intercourse and the efficiency and utilization of medical service determine to a large extent the prevalence of syphilis. The prevalence of the disease is higher among those in the lower economic groups, and evidence from a number of European countries shows a direct relation between economic conditions and syphilis rates. These variations are accentuated by social upheavals such as occurred in a number of countries following the war. The World War resulted in an enormous increase in this disease, which was apparent even in the Scandinavian countries, which were not participants. Alcoholism is another factor which predisposes to exposure and infection.

## TREND OF SYPHILIS RATES

An essential element in judging the success of control efforts, the trend of syphilis infection is difficult to determine. During the past year re-surveys of prevalence have been made in New York State, and in the 14 communities surveyed by the U. S. Public Health Service in 1926-1927, using exactly the same methods in each instance. Detailed data are not yet tabulated for the Service surveys but total cases in the re-survey exceed those found in the initial study.

In 1930 in New York State the total cases under treatment were 15,732, while in 1927 the total was 12,936, an increase of 2,796. The increase was chiefly in clinic cases and in late cases—the early cases being about the same in the two surveys.

Cases notified to the Service, which admittedly represent only a part of treated cases, are not decreasing.<sup>21</sup> In New York State, where current checks are made of all cases diagnosed for the first time in approved laboratories, annual totals show no decline.

Deaths from general paresis and new admissions of this disease to state institutions do not furnish conclusive evidence as to current trends and are complicated by the recently introduced malaria therapy.

Clinicians agree generally that congenital syphilis has decreased. Data from the military forces are inconclusive, with a declining rate in the Army and a stationary rate in the Navy. Space does not permit a discussion of trends and rates in European countries other than the general statement that syphilis increased markedly during and after the war, reaching a peak in 1920 and declining to one-half the 1920 prevalence by 1925-1926. In some countries the rate since then seems to be stationary or on the increase (Harrison<sup>22</sup>), while in others the decline has continued (League of Nations<sup>23</sup>).

Certainly in the United States there is no conclusive evidence that

syphilis is declining. On the contrary, the best evidence available from resurveys of cases under treatment shows a slight increase during the past 4 years.

#### PERCENTAGE OF THE POPULATION PREVIOUSLY INFECTED

A number of students of this problem (Haustein, Jaeger, *et al.*<sup>21</sup>) by a study of annual new cases and known age distribution, have estimated by different methods the per cent of the population at different ages which has experienced an attack of the disease. A fair summary statement is that approximately 20 times the annual attack rate represents the true volume of syphilis infected persons in the community. Haustein has estimated the percentage of persons who between the ages of 15 and 50 have contracted syphilis, varying from 18 per cent in Berlin, to 0.8 per cent for Switzerland. Twenty times the annual attack rate represents for up-state New York a rate of 88 per 1,000; and for the population group given in Table II, 145 per 1,000.

#### EPIDEMIOLOGICAL EVIDENCE OF CONTROLABILITY

Here is a disease in which epidemiological evidence argues for the practicability of control and eradication through direct public health action. Syphilis appears to spread chiefly through a series of localized outbreaks which can be traced to comparatively few determinable sources; the bulk of infection in the white race is concentrated in the cities; most of the cases have a limited period of infectivity; and elimination of infectious sources will have a cumulative effect on the trend.

The existence of an unknown percentage of sub-clinical cases, many of which are infectious, does not in my opinion invalidate the major conclusion. A large proportion of cases are acquired from untreated and inadequately treated cases. These can be recognized by clinical examination and serological tests and can be made non-infectious by treatment.

By these available methods it seems practicable to eradicate syphilis as a public health problem.

## Manuscripts and Poor English

THE scrutiny of hundreds of manuscripts over a term of years makes us sure of our ground when we allege that at least nine of every ten of them could be vastly improved, as literature, by a critical redaction; and of these many stand in very serious need of such redaction.

Not that the violations of good usage are flagrant illiteracies. The flaws are in such things as poor paragraphing; badly constructed sentences, in which two nominatives get to quarreling with one another; plural relatives with singular antecedents, or *vice versa*; the excessive use of trite words and phrases; the use of the wrong word—"due to" (propositional) for "owing to," "advance" for "advancement," "practically" for "almost," the use of unjustifiable neologisms such as "minify"; the use of orphaned or fused participles; the placing of adverbs; failure to recognize a gerund; and so forward to great diversity. In addition, sentences are frequent which, while they exhibit no specific fault, are awkward stumbling blocks for the reader. They require re-phrasing to recapture fluidity. Often a word, ordinarily good, may be used in an unsuitable context. Often poor word-selection needs correcting.

In brief, we discover that most manuscripts would be measurably improved by the ministrations of a word-smith. You will see exactly what is meant if you recall that a word-smith is a word-smoother. One may say perhaps that the difference is that between a shirt that has been ironed and one that has not. To wear the unironed shirt is entirely decent but not sartorially impeccable. # Syphilis in a Rural Negro Population in Tennessee<sup>\*†</sup>

JAMES A. CRABTREE, M. D., AND E. L. BISHOP, M. D., F. A. P. H. A.

*Director, Division of Preventable Diseases ; and State Commissioner of Health,  
Tennessee Department of Public Health, Nashville, Tenn.*

THE fact that syphilis affords the topic of discussion for this program is evidence of the importance that it is assuming in the minds of public health workers throughout the country—suffice it to say that it is second to few diseases in its effects upon the public health.

While it is well to remember that the venereal disease problem has exercised the minds of those charged with the protection of the community's health since early ages, the varied methods of attack, and the changing points of view afford evidence of the unusually complex and difficult nature of venereal disease control.

Fundamental to the control of any communicable disease is knowledge of (1) its incidence, (2) its modes of spread, and (3) the means of its prevention. Without this basic knowledge, control measures will lack that specificity of approach which is regarded as essential to sound procedure.

As regards syphilis, the first requirement, namely, knowledge of its incidence, is for obvious reasons sadly lacking. It follows that knowledge of the means of prevention is also inadequate since this, at least from the point of view of administration, is in part dependent upon knowledge of the incidence.

It is generally believed that the incidence of syphilis among negroes is considerably higher than that among whites, but we have not had sufficiently accurate information to do more than speculate on the extent of racial difference. Indeed we have had practically no information as to the actual incidence in any unselected group of people, either white or black.

During the past year, the Tennessee Department of Public Health has been making a study of syphilis in a rural group of negro families. The study has had three major objectives:

---

<sup>\*</sup> Read at a Joint Session of the Health Officers and Epidemiology Sections of the American Public Health Association at the Sixtieth Annual Meeting at Montreal, Canada, September, 17, 1931.

<sup>†</sup> This study has been made possible by a grant to the Tennessee Department of Health from the Julius Rosenwald Fund.

1. To determine the incidence of syphilis among an unselected group of negroes of all ages
2. To investigate the effects of syphilis upon the negro individually, and as a family unit
3. To determine to what extent negro personnel can be used in a state-wide program of syphilis control

This preliminary report is concerned primarily with the first objective, the prevalence of syphilis in the entire group. Tipton County, Tenn., was selected for study. It is essentially rural with a population of 27,715, of which negroes number 12,028. The family has been used as a unit of study rather than the individual.

Personnel of the field study unit consists of 2 physicians, 1 nurse and 1 office clerk. All are negroes except 1 physician who has acted as director.

A Wassermann survey of an unselected group was made in the beginning, and all positives were rechecked before they were classed as definitely positive.

#### DISTRIBUTION BY AGE AND SEX

Table I shows the age and sex distribution of positive Wassermanns among the entire group tested.

Of 2,323 individuals tested, 602, or practically 26 per cent, are positive. It is of interest to note that approximately 10 per cent of

TABLE I

Total	1,162	263	24.4	1,161	319	27.4	2,323	602	25.9

FIGURE I—Percentage distribution of positive Wassermanns in each age group, in a group of negro families, in Tipton County, Tenn., 1930

children under 15 tested were positive. There is no significant difference as to sex—24.4 per cent males and 27.4 per cent females were positive.

Figure II shows the age distribution of the 602 individuals with positive Wassermanns. Of these, 86.6 per cent are between the ages 15 and 50.

Of the 602 with positive Wassermanns, 526 have been placed under active treatment, which allowed a more detailed study than could be made of the entire group during the preliminary survey. The 76 found positive, but not placed under treatment, were those who for various reasons failed to report to the clinics, on account of moving from the county, death, illness, inaccessibility and failure to coöperate.

Of the 526 cases under treatment and observation, 62 are classed as congenital and 464 as acquired. Thirty-seven of the congenital cases are males and 25 females.

TABLE II

AGE AND SEX DISTRIBUTION OF (1) CONGENITAL AND (2) ACQUIRED CASES OF SYPHILIS IN TIPTON COUNTY, TENN., NEGRO GROUP, 1930

Age	Male		Female		Total	
	Congenital	Acquired	Congenital	Acquired	Congenital	Acquired
0- 4	3	0	6	0	9	0
5- 9	14	0	9	0	23	0
10-14	14	0	3	2	17	2
15-19	2	32	5	35	7	67
20-29	2	74	2	110	4	184
30-39	2	47	0	51	2	98
40-49	0	27	0	30	0	57
50 and over	0	40	0	16	0	56
Total	37	220	25	244	62	464

Table II shows the age and sex distribution of both congenital and acquired cases which were placed under treatment following the preliminary survey. Thirty-one of the 37 male congenital cases are under 15 years of age, and 18 of the 25 female under 15. Age and sex distribution of acquired cases does not differ essentially from what one might expect.

FIGURE II—Age distribution of 602 negroes with positive Wassermann, Tipton County, Tenn., 1930

## RACIAL DIFFERENCES IN PREVALENCE

It has been of interest to compare the incidence of positive Wassermanns among the Tipton County negro group with that among a group of white industrial employees in another section of the state of whom a Wassermann survey was made by the State Department of Health during the early part of 1931. The white survey included 1,712 white males, of 15 to 65 years, among whom 4.3 per cent gave positive Wassermanns. This is to be contrasted with the same age group of Tipton County negroes among whom 32.6 per cent were found to be positive, an incidence of almost 8 times that in the white group.

## KNOWLEDGE OF PRIMARY LESION

Each individual found to have acquired syphilis was carefully questioned as regards history of primary lesion. Table III shows the percentage of acquired cases by sex who gave a history of known primary lesion.

TABLE III

SEX DISTRIBUTION OF CASES OF ACQUIRED SYPHILIS ACCORDING TO HISTORY OF KNOWN  
PRIMARY LESION IN TIPTON COUNTY, TENN., 1930

Sex	History of Primary Lesion	No History of Primary Lesion	Per cent with no History of Primary Lesion
Male	130	90	40.9
Female	65	179	73.4
Total	195	269	58.0

Note that 40.9 per cent of males deny knowledge of primary lesion, while 73.4 per cent of females give a negative history, indicating that the likelihood of infection escaping notice by the female is 1.8 times that by the male. It is obvious that too much reliance should not be placed upon the patient's statement with regard to history of primary lesion, so the actual percentage figures may be too large, but it is not unreasonable to assume that the relative percentages as regards sex differences are fairly accurate; considerably more accurate, perhaps, than would obtain among a group of white people.

It was considered of interest to inquire into the history of each case with respect to gonorrhea. Of the 90 males with acquired syphilis, but denying knowledge of primary lesion, 35.5 per cent gave a history of having had gonorrhea. It is possible that in many instances of syphilis in which knowledge of primary lesion is denied, the infection dates from the time of the gonorrhea. However, no particular signifi-

cance can be placed upon this finding, since it is noted that of all the male cases of acquired syphilis, regardless of history of known primary lesion, 37.3 per cent gave a history of having had gonorrhea; and of the total cases, both sexes, 20.5 per cent gave a history of gonorrhea.

#### DATE INFECTION WAS ACQUIRED

Table IV shows the distribution of cases with history of known primary lesion according to time lesion was acquired. Of the 195 cases, 36 or 18.5 per cent acquired the infection within 1 year, and 52.8 per cent within 5 years.

TABLE IV

DISTRIBUTION OF CASES OF ACQUIRED SYPHILIS ACCORDING TO DATE PRIMARY LESION WAS ACQUIRED. NEGRO FAMILIES IN TIPTON COUNTY, TENN., 1930

Date Lesion Was Acquired	Number of Cases	Date Lesion Was Acquired	Number of Cases
Present Year—1930	36	6-10 Years Ago	33
1 Year Ago	18	11-20 " "	28
2-5 Years Ago	49	Over 20 " "	31
Total			195

It affords interesting speculation to apply the foregoing figures to the total colored population of the county, which is fairly representative of the average southern county. On the basis of findings (26 per cent of the total population, of whom 88 per cent are acquired, 18.5 per cent infected within 1 year) it would seem that in 12,000 there are approximately 2,746 cases of acquired syphilis; and on the assumption that the duration of infection does not differ essentially whether or not the patient had knowledge of primary lesion, approximately 508 cases occurred within 1 year, or an annual morbidity rate for acquired cases of 4,233 per 100,000 population.

#### TREATMENT HISTORY

The treatment history of these cases clearly indicates the magnitude of the problem of syphilis control among negroes which faces preventive medicine. Of the 526 cases under observation, only 73, or 13.9 per cent, had received any treatment. Thirteen of the 73 received neoarsphenamine and mercury, with an average of 7 doses of arsenical and 6 of mercury per patient. Thirty-three received neoarsphenamine only, as follows: 16 received 3 doses or less, 13 from 4 to 6, and 4 from 7 to 13 doses. Four patients received mercury only, 22 received oral or mixed treatment, and in 1 case type of treatment was not stated.

One can then appreciate the apathy with which the average negro views luetic infection, and the problems that a mass treatment project will involve. Too, the need for stimulating physicians to a better type of syphilis practice is quite apparent, when one considers the inadequacy of the treatment given when the negro applied for treatment. In less than one-fourth of instances was the patient likely to be rendered non-infectious for any considerable period of time.

#### STILLBIRTHS AND MISCARRIAGES

The relationship between syphilis and stillbirths is well known. Family histories have been obtained upon all families in the study group and Table V shows the number of stillbirths and miscarriages in relation to the presence or absence of syphilis among parents.

TABLE V

STILLBIRTHS AND MISCARRIAGES IN RELATION TO POSITIVE AND NEGATIVE WASSERMANN IN PARENTS, NEGRO FAMILIES, TIPTON COUNTY, TENN., 1930

Condition of Parents	Number of Pregnancies	Number of Live Births	Number of Still Births	Number of Miscarriages	Per cent Pregnancies Resulting in		
					Live Births	Stillbirths	Miscarriages
One or both Pos. Wass.	859	626	77	156	72.9	8.9	18.2
No Positive Wass. in either	243	235	1	7	96.7	0.4	2.9

In families in which one or both parents had positive Wassermanns, a total of 27.1 per cent of all pregnancies resulted in either stillbirths or miscarriages—8.9 per cent stillbirths, and 18.2 per cent miscarriages. This is to be contrasted with the group in which neither parent is known to be positive (with only 3.3 per cent of miscarriages and stillbirths).

Thus, the likelihood of either a miscarriage or stillbirth, when either parent has a positive Wassermann, is 8.2 times that when neither parent has a positive Wassermann—or the stillbirth rate among parents with positive Wassermanns is 123 per 1,000 live births, the miscarriage rate 249.2; among parents with negative Wassermanns, the stillbirth rate is 4.2 and the miscarriage rate is 29.8.

#### SUMMARY

1. A Wassermann survey of a group of negro families in Tipton County, Tenn., has been made.

2. Of a total of 2,323 individuals of all ages tested, 602 or 26 per cent were found to have positive Wassermanns.
3. Eighty-six and six-tenths per cent of these were between the ages of 15 and 50.
4. Of 562 cases placed under treatment and observation, 62 were classed as congenital, and 464 as acquired syphilis.
5. When persons are infected with syphilis, the likelihood that it will not be apparent to females is 1.8 times that of it not being known to males.
6. Of 195 cases giving a history of known primary lesion, 18.5 per cent stated that the lesion was acquired within the past year.
7. Data collected allow for the estimation that the annual morbidity rate for cases of acquired syphilis in Tipton County, Tenn., is approximately 4,233 per 100,000 population.
8. Treatment of cases is shown to be wholly inadequate.
9. The likelihood of a pregnancy resulting in either a stillbirth or miscarriage when either parent has a positive Wassermann is 8.2 times that of such an occurrence when neither parent has a positive Wassermann.

## Sand in the Sugar

. . . This is, of course, a parable. Sending a manuscript to the type-machines to be transmuted into printed matter when that manuscript is marred with typographical inconsistencies and improprieties is very much like putting a scoopful of sand in the sugar-sack. Ill-advised persons believe that printers exercise some magic by which the blemishes in manuscript are removed. There is no such magic. The sand must be patiently hunted for grain by grain.

Presumably when the author gives "copy" to the printer it is ready to be set into type. The author may say to himself, or even vocally, "They's wunnertwo li'l things in there—but we'll catch that in the proof." The printer knows that in at least nineteen cases of every twenty, there are not merely one or two but many times that number. "But (he may reflect) that's the author's funeral. He's paying for authors' alterations, I'm not. Or if he wansta lettem lie, why should I worry? What's the diff, anyhow?"

And so author and printer enter into a conspiracy to put sand in the sugar—"sand" that, once it gets into type, can very seldom be entirely sifted out. And neither printer nor author thereafter has the privilege of saying what guest shall eat of the feast they have prepared. Any literate person can read their product. Perhaps many of them will not be sensitive to the improprieties. But the most discriminating reader will; and that's the reader that the author particularly (it may be supposed) wishes not to insult.

It is no easier to take the "sand" out of manuscript than it is to take it out of proof. But it is very much simpler to do so and in consequence the doing is more efficacious. And it is very much cheaper, for it can be done, ordinarily, with pen-strokes. The author is serving both his pride and his purse if he has it done in manuscript rather than if he waits until the cost appears in "authors' alterations." "Homily on Sand in the Sugar," Waverly Press, Inc., Baltimore, Md.

# The Control of Syphilis from the Health Officer's Viewpoint\*

N. A. NELSON, M. D.

*Division of Communicable Diseases, State Department of Health, Boston, Mass.*

SYPHILIS has been known in modern history for more than 400 years. In that time it has become, except for the common cold and gonorrhea, among the most prevalent of communicable diseases. The *treponema pallidum* has been known as the causative organism of syphilis for 25 years. The Wassermann reaction has been available as a laboratory aid in the diagnosis of syphilis for 24 years. The arsphenamines have constituted the keystone of anti-syphilitic therapy for 16 years. What other disease would so long have been ignored in the face of so complete an armamentarium! Someone has said that if syphilis were only coughed and sneezed it would have been wiped out long ago.

The *treponema* is delicate and lives only on moist surfaces; there is no intermediary host, the disease being spread from person to person by only the most intimate of contacts; there can be no explosive outbreaks; for control purposes only that part of the population between 15 and 45 years, and especially between 20 and 30 years of age, need be considered; the disease is, in most instances, openly communicable only for a few months at most, even when untreated; the diagnosis is easily made by methods which are readily available and remedies are everywhere at hand which will quickly sterilize the patient.

Yet where are we in the control of syphilis?

Among health officials there are a few who are striving to secure its recognition as a major public health problem. Associated with them are the social hygiene associations and a small group of physicians who are as interested in the control of syphilis as they are in the more technical matter of its treatment. It is the rare city health officer who pays more than passing attention to the incidence of syphilis in his community. Too often it is necessary to plead against his reduction of the next year's budget for the "venereal disease" clinic. In the smaller cities and towns the usual reaction to this enormous

---

\* Read at a Joint Session of the Health Officers and Epidemiology Sections of the American Public Health Association at the Sixtieth Annual Meeting at Montreal, Canada, September 17, 1931.

problem is poorly disguised irritation over the unwelcome responsibility for following up the occasionally reported patient who has lapsed treatment, or the even more rarely reported source of infection.

There are clinics here and there; some worthy of the name, but more often overcrowded; poorly organized; indulging in routine, mass treatment; lacking any semblance of privacy; operating at inadequate and inconvenient hours; and understaffed with a personnel compelled to think in terms of minutes per patient to the exclusion of any intelligent or sympathetic instruction of the patient. Follow-up of delinquent patients, contacts and sources of infection is more often lacking than not, and where it exists it is too often perfunctory, unsympathetic and irritating. Many of the clinics are operated by private hospitals without the least support or even attention from the local health officials, although syphilis is a major communicable disease.

Demand for public information concerning syphilis comes from so few, scattered individuals that almost without exception newspaper editors can safely lean back in their chairs and get away with the fatuous argument that since their reading public must be protected from the unpleasant, they cannot print anything about so indelicate a subject as the "social diseases."

The idealist, sitting safely at his desk, insists that there is no reason why syphilis should not be managed exactly as any other communicable disease. He argues that one needs only to remember that syphilis is a communicable disease and to forget its moral implications, which, in many cases, do not apply. But the health officer who must ring the delinquent patient's doorbell without arousing the curiosity of the family, or who has just advised an examination to an indignant "source of infection," discovers that a natural human desire to avoid discovery of sex irregularity is not so easily brushed aside by an idealistic wave of the hand.

There are excellent reasons why the official program for the control of syphilis should not be as broad as the whole field of social hygiene. Syphilis is but one product of social and sexual ignorance and family maladjustment. If syphilis were to cease to exist tomorrow there would still remain the need for repressing prostitution, for safeguarding morals, for solving the problems of illegitimacy, for providing adequate recreational outlet for youthful energy, and for improving family relationship. Social hygienists have entered the lists against syphilis, first, to set the example to the official agency and second because the more concretely measurable and more immediately remediable part of their problem happens to be communicable disease. The health department which attempts to control syphilis by solving

the fundamental problems of social conduct will not only dissipate its energies to the point of ineffectual thinness, but will soon become discouraged at the slow progress which is being made. It would be as simple to control diphtheria by attempting so to adjust social relationships that the upper respiratory discharges of one person could not possibly reach the upper respiratory tract of another. The control of syphilis is not in any sense dependent upon a social revolution or reconstruction, as is demonstrated in some of the smaller European countries where it is rapidly being accomplished. While the official health agency may well participate in, and give support to, the broader program, its first responsibility is that of applying what is known about syphilis as a disease to its control as a disease.

Among the more important parts of such a program are epidemiology, medical care, public education, and health administration. Underlying these, and essential to the authority of the health department to proceed with its program, is the law.

Almost every attempt at arbitrary law enforcement only adds to the evidence of its futility. Syphilis is easily hidden and easily driven to cover. It is not, like typhoid, an acute and promptly incapacitating disease, nor like smallpox both acute and visible. In most communicable diseases the doctor is called to the home. The name and address of the patient are readily obtained. Isolation and quarantine follow immediately and continue throughout the duration of the disease. The neighborhood is aware of the illness and demands rigid adherence to the regulations. The time factor is short. There is no public disgrace associated with having the disease.

The patient with early syphilis is rarely sick enough to call the doctor; he goes to the doctor's office. In Massachusetts, nearly 25 per cent go to out-of-town physicians for treatment. If syphilis is suspected, a false name and address may be given. There is no isolation or quarantine. The disease is readily hidden from even the most intimate members of the patient's immediate family and there is usually adequate personal desire to keep it hidden. If the physician has failed to instruct the patient, nobody knows it. Adequate treatment requires months and years and the cost is often excessive. If the patient stops treatment the physician rarely reports the fact, and if he does the chances are equal that the patient may or may not be found. It is almost inconceivable that the time will ever come when a person will openly admit his infection and allow the authorities publicly to supervise his conduct and his treatment until he is no longer dangerous.

Any law or regulation, therefore, which attempts to force the syphilitic into the open will succeed only in driving him to the cover

of the drug store, the charlatan, the unscrupulous physician or to no treatment at all. Treatment cannot be made compulsory for the patient who declines to be discovered, or who, feeling the heel of authority about to descend, decides to lose himself under a false name or a changed address. Compulsion must be reserved for the relatively few who are feeble-minded, vicious, or criminal exactly as in tuberculosis. Even then, whenever possible, the direct action should be aimed at the antisocial behavior rather than at the diseased condition of the patient.

Further, there is no method by which the patient's conduct may be supervised outside the physician's office or the clinic, and while regular treatment shortens the period of open communicability there are innumerable instances of exposure to infection by a patient under treatment. The isolation of every patient with syphilis until he can under no circumstances transmit the disease is economically impossible even conceding that the patient, knowing that he would be isolated, would permit his infection to become known.

The control of syphilis, therefore, must depend upon the extent to which the patient can be trusted. How well he can be trusted depends a great deal upon how carefully he has been instructed. If our clinics almost invariably neglect this most important matter, what must the situation be in the busy, unsympathetic and often therapeutically ignorant doctor's office!

Even in the matter of reporting, compulsion has little success, since it is easy for the uncoöperative physician to deny having made the diagnosis, and difficult to persuade the patient to testify at any hearing as to his condition. A few months ago it was discovered that several physicians had failed to report a single case of gonorrhea although they had received several reports of positive smears from our state laboratory. Letters were written suggesting that the cases be reported. Later investigation disclosed, not improved reporting, but termination of the use of the laboratory.

A storm of protest followed a regulation requiring that certain printed instructions be given by the physician to every patient with syphilis. Some of this was justified, for none of the available literature suits every type of case. When the regulation was removed and the literature simply offered to the physician by way of sample copies mailed to each one of them, the demand for it was both prompt and general. How many states which order physicians to give their patients these printed instructions have any evidence that the regulation is generally obeyed? There can be too much arbitrary telling the physician what he must do and too little of letting him work out the

problem, as an intelligent individual, with the health officer. The thoughtful health officer is more interested in results slowly but surely achieved than in the empty ring of his "billy" on the midnight air.

Authority, then, should be given to health officers to make epidemiological studies and to develop a program for the control of syphilis. Resources should be given health officers to provide services, aid clinics, maintain hospital beds, and make adequate diagnostic and therapeutic care available. The regulations of the boards of health should define the manner in which these services may best be utilized, but should not be so irritating and so arbitrarily enforced that they defeat their purpose. There has been little of compulsion in the control of tuberculosis. Progress in the solution of that problem has been almost directly in proportion to the number and quality of the services which have been made freely available to both the physician and the tuberculous.

Epidemiology is the bookkeeping of public health. Until the reporting of syphilis becomes more nearly complete it will be difficult to measure the whole length and breadth of progress, but generations of public and medical prejudice will not be overcome by the overnight decision of the health officer to have syphilis reported. There is no need to wait for more evidence before proceeding with a program. It is picayunish so to insist upon rule-of-thumb administrative procedures that the main object is defeated.

Among the first things necessary to improve reporting is to modify the cumbersome and complicated reporting systems. One health department has forms as large as business correspondence stationery. It would take 10 or 15 minutes to fill one out completely and intelligently. The 16- or 20-page book of detailed regulations accompanying the forms would puzzle an expert if he had time to read it. Another has no less than 11 forms to be used for reporting this or that. The physician would be remarkable who even knew he had all of them, let alone how and when to use them. The minimum number of forms in current use seems to be 5; 1 each for gonorrhea, syphilis, 1 reporting a delinquent patient, notifying a former physician of the patient's change of medical adviser, and reporting the source of the patient's infection. Is it any wonder that the average physician, surrounded on all sides by birth certificates, death certificates, liquor prescriptions, narcotic blanks, questionnaires, other communicable disease reports, unpaid bills and income tax reports, balks at this further complication which, so far as he can see, serves no other purpose than telling the health officer something about which nothing is ever done?

In Massachusetts, 1 form has been devised to serve every purpose,

and business reply envelopes are provided so that there is no expense to the physician for postage. This simplification of the reporting system was responsible in no small part for an increase from less than 6,000 to more than 11,000 reports in a single year.

There is no essential administrative value in requiring the name of the coöperative patient. Nothing is done about it except possibly to discount duplicate reports. Requiring the name discourages reporting and encourages the use of aliases. Let the report serve simply for the collection of the maximum of essential epidemiological data, which can be obtained with a minimum of irritating inconvenience to the co-operating physician.

Under the subject of medical care there are to be considered:

1. Adequate treatment of the patient in the physician's office and in the clinic
2. Follow-up of the delinquent patient, contacts, and the source of infection

Adequate treatment for the patient involves the undergraduate and postgraduate training of the physician in anti-syphilitic therapy and public health procedure, the provision of Wassermann laboratory service and dark-field examination, a readily available supply at least of arsenicals for every patient, adequate free or part-pay clinic service at convenient hours and with sufficient personnel to give the necessary time to the patient. It is necessary to educate the public to suspect every promiscuous intercourse as being a contact with infection, to realize the importance of adequate treatment begun soon after infection, and the wisdom of premarital examination and routine Wassermann examination in every pregnancy.

Physicians are not entirely to blame for their general unfamiliarity with anti-syphilitic therapy, but the medical profession can correct the situation by insisting upon adequate instruction, in the future, in the medical schools. For those already out of school, other provision must be made, since specialists will never adequately cover the ground. Demonstration clinics, talks to medical societies and hospital staffs, postgraduate clinic courses, brief, up-to-date texts on the management of syphilis, constant reminders, in one way or another, of the communicability of the disease, all help to keep the subject alive. The more rapidly the public is taught what to expect in the way of anti-syphilitic treatment, the more rapidly will physicians have to increase their knowledge and improve their technic.

In Massachusetts, one trained member of the department is making office-to-office visits to every physician in the state, calling attention to services, discussing cases, talking treatment, listening to sug-

gestions as to how services may be improved, accepting complaints, and in every way possible attempting to interest the physician and discover how he can be made a more willing and better equipped partner with the department in its program. In this we are following the example of Dr. Coombs and the Maine Health Department.

Every state should have adequate and accurate Wassermann laboratory service, freely available. Dark-field examination service is more difficult to provide, for no method has been devised which obviates sending the patient to the laboratory; yet this procedure is the only one upon which a diagnosis of primary sero-negative syphilis can be made, and treatment begun in this stage leads in almost every case to cure. No clinic should be without dark-field equipment and a competent observer, and it should serve as the diagnostic center for its area.

There is some debate as to how far the state or the local board of health should go toward supplying all the medication necessary, in early syphilis at least. Some board of health clinics treat patients only during the openly communicable stage. This is, of course, worse than useless, since inadequate treatment leads to relapse and even greater communicability. Some states provide arsenicals only for the treatment of the indigent. This results in red tape and the neglect of those who decline to be officially recorded as paupers. Certainly there can be no good reason why the arsenicals, which are the chief sterilizing agents; should not be made as freely available to any physician for any patient as is antitoxin for diphtheria. Logically, either bismuth or mercury should also be provided, since arsenicals cannot be given continuously, and these other products are essential to adequate treatment if the disease is to be kept non-communicable. However, if arsenicals are available treatment may be begun and there will be some time in which to make whatever economic adjustment may be necessary for its continuation.

There is much to be desired both as to the number of clinics which should be maintained and the quality of their services. Unfortunately it is usually impossible to operate a clinic successfully in a community of less than 30,000 or 40,000 people because of public curiosity. How to provide this service for large areas composed of small cities and towns is still very much a problem. At any rate, there is ample room for improvement in the clinics that are now being operated. There can be little comfort in being forced by economic circumstances to sit with a hundred others for an hour or more, on hard benches, in a barren waiting room, with nothing to read or do, until an impersonal clerk calls out a number, becomes irritated if you have dozed and are slow

to respond, then crowd into line with a dozen others in a small room, let down your trousers or lift up your skirts as the case may be, to receive, almost in full view of the rest, a jab in the buttocks, and be dismissed with the routine admonition, "come back next week." Not a smile, not a kindly word of explanation to set your fears at rest. No one to tell you whether next week's treatment is the last or only one more in a life-long series. A mysterious business, a barren place, an impersonal, repelling atmosphere, and a bawling out if you cannot see the sense of attending any longer. If physicians' offices were managed in this manner, there would be no patients in them. Yet we expect by these methods to control a dangerous communicable disease in a patient on whom our only hold is his confidence in us and his trustworthiness.

Adequate treatment cannot be defined, however, as that which the patient receives after he has come to medical attention, unless he has come in time. No matter how thoroughly competent physicians become, nor how luxurious and complete our clinic service may be made, so long as 2 out of every 3 patients begin treatment only after a year or more has passed since infection, there can be little adequate treatment; and since the disease is most highly communicable during the first year, there can be no progress in its control. Thus there must be public education.

The follow-up of the delinquent patient is a serious problem. It is almost impossible to persuade physicians to report the delinquent. This may be justifiable in small towns where the report of a name to the local board of health may prove extremely embarrassing to the patient. It can also be appreciated that the physician is almost certain to lose permanently any patient whom he causes to be visited by the health officer. It has already been pointed out that half the patients who are reported cannot be found. After listening to the accounts of some health officers of their "capture" of some delinquent patient and their window-peeping methods on the trail of a source of infection, I have lost some of my faith in the advisability of turning this delicate problem over to untrained and insensitive persons. They are apt to threaten where only tact is needed; they may accuse when only sympathetic understanding will clear the path to the doctor's office; they sometimes ask the unsuspecting wife why the husband has neglected to go to the clinic; they have the common belief that syphilis is synonymous with sin and they become police officers rather than health officers.

It is a matter of record that a competent, sympathetic medical social worker in a clinic not only will reduce delinquency to a minimum,

but will secure the examination of many of the family contacts and a large proportion of the identifiable sources of infection. I doubt that, except in rare instances, any health officer could do anything for or with a delinquent that a good medical social worker has had to give up. If it is worth while to provide good medical social service in clinics, why not apply the principle to the whole problem of the delinquent patient?

Suppose the reporting of these patients and sources of infection be entirely discontinued, and the physician be permitted instead to call for the service of a medical social worker. Communicable disease nurses and tuberculosis nurses are now employed by most boards of health—why not a specially trained nurse to visit syphilis patients? But instead of making her visit one of public record, let her make the doctor's office her starting point and let her forget the identity of the patient when she has reported back. The principle is exactly the same, only the route taken is different and the training more specialized. The patient cannot resent the tactful, private approach of a woman representing, not the board of health, but the doctor, who explains why treatment may not safely be neglected. The physician has no cause for complaint at the return of his patients, even though a few, unable to pay his fee, may have been referred, with his permission, to a clinic. The board of health will have established no new type of service since it already visits in case of other communicable diseases, and its object, to keep patients under treatment, will be accomplished far more satisfactorily than would be possible by any other method. True, the patient's name does not become official property, but that may be dispensed with to no administrative disadvantage. This method of follow-up has been tried in some 50 cases in one physician's practice in Massachusetts, to the complete satisfaction of everybody.

We know the cause and mode of spread of syphilis. We have the means for its diagnosis. We have an effective therapeutic agent. We know enough about its epidemiology to warrant unusual effort for its control. We can see that it cannot be controlled by rule-of-thumb procedures. Let us, then, shape our program to our problem and stop begging the problem to be reasonable.

**F**IND me a man whose syntax is snarled and I'll show you a man whose thinking is also snarled. Lame English runs neck and neck with spavined logic.

MENCKEN

# When the Doctor Prescribes Books<sup>\*</sup>

CATHERINE POYAS WALKER

*Librarian 4th Corps Area, U. S. Army, Atlanta, Ga., Member American Library Association Hospital Libraries Committee*

WHEN the doctor prescribes books, the hospital library, whether owned by the hospital, supplied by the city libraries, or by the federal or state governments, must stand ready to fill the prescription. While to the casual observer the books carried to the patient may appear to be given out in an almost haphazard manner, there is no greater care taken by librarians than toward eliminating the wrong ones from hospital libraries, and insuring the right book for the right patient, in order to bring about the therapeutic value of well chosen reading.

That the selection of books for their curative value is necessary in hospital libraries would seem apparent. It is the purpose of many of the hospital librarians to cumulate and formulate what they have learned from their individual experiences in order to eliminate difficulties for others. As a suggestion, it would seem advisable that they turn their attention toward the formulation of a mental and psychological symptomatology of various diseases, which would be of enormous value in hospital libraries, while in them the physical characteristics of illnesses are of lesser importance, besides being readily available from the hospital records on each patient.

Doctors in charge frequently help librarians by describing individual mental symptoms of particular patients, which are of the utmost value in prescribing suitable books, and these specific instances would seem to prove the need for the general psychological symptomatology. This would be to the hospital library what the general symptomatology is to the physician. Individual application in every case would remain necessary, for the librarian as well as the doctor.

The large public library, with its great demands from readers of every character, provided it has a fairly adequate book fund, presents few problems in book selection, since it buys practically every book published, leaving the selection to the discrimination and interests of the reader, with the advice of the staff when needed.

The hospital library, as a rule, has a very limited book fund, which

<sup>\*</sup> A Psychological Symptomatology Advocated to aid in Bibliotherapy.

may, at first glance, appear reasonably adequate, as a hospital contains but a small number of readers in comparison with that of a great public library; yet, every type of reader belonging to a large public library is likely to become one of the readers in the hospital library. Consequently, upon a small book fund, the hospital library must attempt to furnish interest for everyone, from the patient whose daily labors provide no time for reading except when confined to bed, to the omnivorous reader who keeps up with the latest book criticisms and demands the latest selections of the various book clubs, or who even considers those out-dated. The enforced idleness of hospitalization frequently makes readers out of patients who, outside the hospital, would prefer other occupations and diversions.

Interest is the first requisite in all curative reading. No patient will open his eyes and quickly swallow a sugar-coated book because advised of its remedial value. Indeed, unless a book creates interest, it is greatly to be questioned whether it will have therapeutic qualities—unless, perchance, irritation were what the doctor prescribed. While the seldom-reading patient is probably easily satisfied with material at hand, the voracious and sophisticated reader, accustomed to large collections of books, and frequently resenting suggestions, often presents a more serious problem in hospital libraries, usually necessarily small.

There are several general aspects to be considered in book selection for the hospital library. A book which may be helpful, or at least harmless, in one ward, may be very harmful in another. Then there is a general psychological symptomatology to be taken into consideration before prescribing a book. There are obvious, generally well known, blanket rules for book selection in various hospitals; for instance, in the penitentiary hospitals, mystery, crime, and detective stories are usually banned; in mental hospitals, the mere mention of the word "crazy," however apparently harmless its context, may have an unfortunate effect; tuberculous patients should have cheerful books; and so forth. Concerning the books themselves, in general, those dwelling upon, and describing disease, ill or deformed characters, must be avoided; to some patients the subject of finances is one of great matter, and even humorous accounts of attempts to secure money may not seem amusing to them. One man's humor is another man's grief, might well be the epigram for the hospital librarian regarding so-called humorous books, and the same caution applies to the "cheerful" books—there is usually nothing more annoying to patients than an enforcedly and persistently cheerful book or person. The old-fashioned novel demanded by some readers will not be tolerated by

others. On the other hand, the hospital might find its curative purpose rather defeated if the librarian gave its patients certain modern novels, the trend of which would seem to be the utter futility of living. The therapeutic value of the writings of many of the young sophisticates who believe that by intuition they have grasped new wisdom unsuspected by the ages, is also questionable. A book with a persistent dwelling on sex is not usually conducive to good health. Introspective books, those dealing with family squabbles, marital difficulties, suicides, gruesome and horrible details, problems of various sorts, and religion are dangerous topics to present to some readers, who may be shut up in one small room for an indefinite period. For instance, one very ill patient to whom a kind hearted friend gave a copy of "Dracula," suffered from increased temperature and sleeplessness after reading it.

The casual reading of a book is not sufficient to determine its fitness for a hospital. For instance, a covered-wagon novel of the western march of a family and caravan appeared to be excellent hospital material, being well told, with graphic descriptions of outdoor life on the trail, hardships courageously met, of sufficiently probable, yet not too gruesome relations with the Indians; but suddenly toward the end the author described the birth of a baby. While, for hospital readers, there is nothing harmful in that of itself, and there was no undue dwelling upon clinical details, yet the fact that anxiety over a missing husband, and lack of care to the mother, made her become "addled," would make this book dubious reading for a maternity ward, or a psychoneurotic patient, and would quite overcome the pleasant outdoor interest of the early chapters. Even the facts that the husband eventually returned, and the wife's mind became restored might not counteract the disagreeable episodes; yet for a reader not in a hospital, this is an interesting story.

Another recent novel dwells upon the problems of the parents of a dwarf, again, scarcely suitable for most hospital patients. It is to be doubted if Willa Cather's *Shadows on the Rock*, though it will be requested by many patients, will be a good prescription, on account of the deformities described, one resulting from the suppuration of a wound due to neglect; the Indian and prison tortures, and similar horrors of prisons and man's inhumanity to man, the very excellence of the writing but serves to make more graphic.

Censorship is abhorrent in thought to most librarians; yet it would seem—with the object of restoring patients as rapidly as possible, through the entertainment, recreation and fellowship of books—even the general hospital library books must be selected with the greatest

care, and that in addition, the hospital librarian must give individual diagnosis to the reading prescription, and thought, not only to the general symptomatology and to the causes responsible for it, but also to the particular needs and fancies of each patient, preventing, as does the pharmacist, the indiscriminate use of what might be poison in some instances, yet have therapeutic value in others. The ideal situation is not to restrict the books placed in the hospital library, but to limit their use to patients.

It cannot be overemphasized that the proposed psychological symptomatology would no more relieve the librarian's responsibility from individual reading diagnosis for each patient, than does a general symptomatology relieve a physician from the consideration of each patient. Yet as a physician can use the general as a basis from which to particularize, so it is believed might the hospital librarian find the advocated psychological symptomatology a great help, when, with the aid of hospital librarians, psychiatrists, psychologists, mental hygienists, and others interested, such a book can be compiled.

In the case of the general hospitals the book might be prepared to answer such questions as: Does angina pectoris, for instance, require a different mental diet of books from some other "heart diseases"? Are the patients suffering from it not to be given exciting detective novels, with gory detailed accounts of murders, or, if the patient demands them, should the librarian furnish such reading rather than try to dissuade him or offer substitutes?

If a patient with Bright's disease is irritable, does it go with the disease, or is it peculiar to the particular patient? If it goes with the disease, is the irritation continuous or spasmodic? Is there hope of cheerful books proving a corrective for a depressed outlook?

If a certain amount of irritation naturally accompanies a physical disease of a certain name, the librarian might have a more scientific basis of knowing when to be slightly insistent in offering books to a new patient who gruffly refuses to take anything offered, and appears to have a general grouch against everything. Some patients really want to be urged a little. Some are not sure they will not have to pay for the books. Naturally, the last object the librarian has is to annoy the patients in any way whatsoever, but the selections might be slightly more scientific than those now made on just intuition, tact, or general guess work.

Abnormal psychology is not needed for general patients who are not really abnormal, but frequently conditioned mentally by physical states requiring a long shut-in period. Some short-cut is needed for hospital librarians to find out the mental states that accompany the

various diseases, without studying the physical conditions involved, and without appealing to overworked doctors to help them out.

In the case of the mental hospitals, the selection of a book, representing a series of mental stimulus involving various reactions, means an almost overwhelming amount of individual knowledge concerning the problems of a particular patient and the causes of his condition—if they can be learned—to be sure that the effect will be beneficial. Consultation with the doctors in charge is frequently, and almost invariably necessary. The mental hospitals require librarians as specially trained as psychiatrists rather than “family physicians.” Yet what is to provide that special training for librarians who cannot in most instances become also psychiatrists?

In any hospital, mental or general, the human element, the individual, would always have to be considered—whether his hatreds were ghosts or finances, family problems, too much mother-in-law, or what-not; whether he prefers golf or baseball, art or engineering, or whether all professional reminders are taboo during illness; or in the case of a woman, whether she prefers a sweet love story, or a problem novel, or it takes something very “sophisticated” to arouse her interest, or if any mention of sentiment is to be avoided altogether.

As a basis upon which to train all hospital librarians, as a textbook for their training, and as their reference foundation from which to start their diagnoses to aid their patients, in a general hospital and even in a mental hospital, it is believed that the proposed psychological symptomatology might provide that foundation and generalization from which any hospital librarian might work toward individual understanding of the book needs of each of her patients.

---

## The Greatest of These is Health

WHATEVER else might change, it remained true that among the assets on which we had to rely in the new advance there was none so rich as the health of the nation. Economy was one thing, parsimony another. Economy enriched; parsimony might impoverish. Economy demanded the development of national assets so that each might give the greatest return to the nation. The return on no asset of the nation could be more increased by development than the return on the asset of health. The common health was the very foundation on which all fresh effort must be built, the base from which all advance must proceed. “Health, liberty, and wealth, and the greatest of these is health; for if a nation has that, the others will be added to it.”—Sir Hilton Young, Minister of Health, *Med. Off.*, Nov. 28, 1931, p. 234.

## SIR DAVID BRUCE

NEWS of the death of Sir David Bruce comes to us from abroad. Born in Australia, he was educated at Edinburgh University, and became a member of the Army Medical Service in 1883. From 1889 to 1894, he was Assistant Professor of Pathology at the Army Medical School, and later, for 4 years he edited the *Journal of the Royal Army Medical Corps*.

Sir David Bruce was one of the early workers in tropical medicine, and is justly regarded as one of the founders of that branch of our science. His first work which brought him into notice was the discovery of the cause of Malta fever, which produced much invalidism in the naval forces of England in the Mediterranean and great loss of money. He showed that it was carried by the goat through the milk, and discovered the germ known as the *Micrococcus melitensis*. He made investigations of nagana and tsetse fly disease, showing that they were one and the same, due to a trypanosome which was carried by the tsetse fly. This is believed to be the first instance in which an insect was shown to be the carrier of a disease producing protozoan parasite.

The Royal Society in 1903 sent him to Uganda to study trypanosomiasis in that stricken country. Castellani had shown that the trypanosome was found in the spinal fluid in cases of sleeping sickness. Bruce went further and proved that the organism was the cause of the disease, and later that the *Glossina palpalis* was the carrier of this

particular trypanosome, the distribution of the disease corresponding with that of the fly.

During the World War he was chairman of the committee on tetanus, and later chairman of that for the study of trench fever. Many honors were conferred on him by universities and societies, and it will be remembered that the trypanosome of nagana bears his name.

His passing at the age of 74 takes away one of the founders of the science of tropical medicine.

### DR. PETER H. BRYCE

THE death of Dr. Peter H. Bryce, of Ottawa, Canada, will sadden every member of the Association, removing from us, as it does, one of our oldest members—he joined the Association in 1883. He became President in 1900, after having served on various committees and held other positions of usefulness and honor in our Association. In recognition of his services to the Association, he was elected an Honorary Fellow in 1922.

Dr. Bryce was honored and beloved by all who knew him, genial in character, honest, and outspoken. A long career of usefulness in his native country in various positions led to a pension soon after the World War.

The newspapers tell us that he died on board ship while seeking a rest in a warmer climate. A fuller history of his activities will be given in our next issue. "Requiescat in pace" will be the earnest prayer of all those who were fortunate enough to know him.

### VOLUNTARY EUTHANASIA

THE question of euthanasia has been discussed for many years. There are many things in it which appeal to everyone, but so many objections to it, legal and otherwise, that it has not been generally accepted.

The newly elected President of the Society of Medical Officers of Health of England gave as his Presidential Address' a most interesting and scholarly discussion in which he advocated the legalization of voluntary euthanasia, and outlined the essential provisions for such an act. His proposition is that individuals of proper age and mentality who are suffering from incurable and fatal diseases which entail a slow and painful death should be allowed to substitute a quick and painless one, after complying with certain conditions. He regards this not only as an act of mercy, but "as a matter of elementary human right."

His discussion of this question shows much research and clear reasoning, taking up, in turn, the fear of death, the legality of suicide, the Christian attitude toward it, ethical and practical objections. Many readers will doubtless be surprised to learn of the attitude of prominent churchmen in the past, and one, Canon Green, makes a statement which is hard to answer: "One might, of course, argue that as God alone confers life, God alone may decree its end. That argument, however, is impossible while we permit war and capital punishment. . . . I have found it impossible to discover any really conclusive argument against suicide under due restrictions."

Recently, Dean Inge, who is well known for his writings on religious and ethical subjects, has shown a distinctly sympathetic attitude toward euthanasia, pointing out the anomaly of putting a horse or dog out of its misery, but undergoing the danger of hanging for helping a patient suffering with cancer with an overdose of morphine. He closes, however, with the statement that if he should ever suffer from such a disease he hopes that he would have patience to await the end.

It is generally held that suicide is an act of moral cowardice, and in many cases this is doubtless true; a father, for example, leaving a dependent wife and children without means of support. It has been condemned in many countries—in fact it is a criminal act in some, and an unsuccessful attempt often leads one into the courts for punishment, which has included the confiscation of property. Further, suicides have been denied Christian burial as well as interment in consecrated ground. For centuries suicides were buried at crossroads with a stake driven through the body, and this was discontinued in England only 50 years ago.

The religious side is based largely on the command "Thou shalt not kill," which has been revised to read "Thou shalt do no murder." The Fathers of the Church interpreted the original version to include one's self in the order against killing, and the early Christians took the view "it was desertion of a sacred trust without permission of God."

Euthanasia has very properly been objected to on legal grounds as opening the door for murder. Voluntary euthanasia as outlined by Dr. Millard would apparently be free from this objection. Cases arise frequently in which the hearts of the family of a sufferer are torn by conflicting emotions. In this country a short time ago we had the case of a father who, feeling that his end was near, put to death his incompetent daughter to whom he had devoted his life, his object being to make sure that she would not suffer from neglect at the hands of those to whom she was not dear. The current papers are carrying

the story of a woman in Copenhagen who deliberately overdosed her mother, Baroness Von Dueben. The judge in this case is said to have viewed the case leniently, being convinced that there was no malice and that the action of the daughter was founded in love and the desire to end hopeless suffering.

On the other hand, in certain countries and under certain conditions, suicide is considered an act worthy of commendation. It has always been regarded as praiseworthy for soldiers and sailors to die rather than surrender, and even to put themselves to death to avoid capture. In China it is honorable for women to kill themselves at the death of their husbands, and in Japan suicide may be legally done to avoid disgrace, to restore honor, as a matter of protest, and from loyalty to a superior. Many will remember the death by hara-kiri of one of Japan's foremost statesmen only a few years ago.

Doubtless the Presidential Address of Dr. Millard will cause much discussion and bring protests. The great majority of the people of the western nations, at least, are not ready for such an innovation, but no one can read it without learning much, and for many we believe that it will help to do away with the practically universal fear of death, which the late Professor Metchnikoff held was given to us for the preservation of the species.

"The great task of Medicine is to prevent disease; and failing that, to cure disease. If it fails in both, science, at least, enables us to shorten the sufferings caused by disease."

## NEW MEMBERS

*The following list includes applicants who have been approved for membership in the A. P. H. A. by the Sub-Committee on Eligibility. These new members have requested affiliation with the sections indicated, and action by the Section Council will follow.*

### *Health Officers Section*

Manuel R. Benitez, M.D., Dept. of Health, San Juan, P. R., Assistant Director, Bureau of Communicable Diseases

Ramon B. Berdecia, M.D., Box 1266, San Juan, P. R., General Medical Inspector

F. R. Dew, M.D., St. Clairsville, O., Health Commissioner

Cesar Dominguez, M.D., P. O. Box 92, Humacao, P. R., Medical Officer

T. Paul Haney, Jr., M.D., McComb, Miss., Director, Pike County Health Dept.

Dr. M. R. Kinde, Hastings, Mich., County Health Officer

A. D. Park, M.D., Hartford, Ky., Director, Ohio County Health Unit

John H. Williams, M.D., Suites 2 & 3, Neely Block, Muncie, Ind., City Health Officer

### *Laboratory Section*

Carl A. Nowak, Nowak Chemical Labs., 1327 Chemical Bldg., St. Louis, Mo., Laboratory worker

### *Vital Statistics Section*

Elliott H. Pennell, U. S. Public Health Service, Washington, D. C., Assistant Statistician

Manuel A. Perez, Bur. of Vital Statistics, Dept. of Health, San Juan, P. R., Chief

### *Public Health Engineering Section*

Herman G. Baity, Sc.D., Dean, School of Engineering, Univ. of North Carolina, Chapel Hill, N. C., Professor of Sanitary and Municipal Engr.

Pedro M. Otero, Dept. of Health, San Juan, P. R., Engineer, Bur. of Malaria Control

Ralph M. Palmer, 10 E. 40th St., New York, N. Y., Chemical Engineer

Walter Spencer, S. Jersey Assn. of Water Supts., 7220 Walnut Ave., Merchantville, N. J., Asst. Supt., Merchantville-Pennsauken Water Comm.

### *Child Hygiene Section*

Marta Robert de Romeu, M.D., Parque St. 91½, Santurce, P. R., Director, Bur. of Child Hygiene

### *Public Health Education Section*

Mildred I. Dillistin, City Hall, Middletown, N. Y., Asst. to Health Officer

Marie F. Kirwan, 245 E. 21st St., New York, N. Y., Extension Secty., New York State Comm. on Tuberculosis and Public Health.

### *Public Health Nursing Section*

Helen S. Orth, R.N., Mt. Vernon, Ky., County Health Nurse

Bosse B. Randle, R.N., Bd. of Ed., 143 Bostwick, N. E., Grand Rapids, Mich., Supv. of Nurses

### *Epidemiology Section*

Abel de Juan, Dept. of Health, San Juan, P. R., Dir. Bur. of Comm. Disease

### *Unaffiliated*

Antonio Arbona, M.D., P. O. Box 221, San Juan, P. R., Medical Officer, Bur. of Malaria Control

Jose R. Pastor, M.D., Dept. of Health, San Juan, P. R., Director, Bur. of Tuberculosis

### DECEASED MEMBERS

J. S. Fulton, M.D., Baltimore, Md., Elected Member 1915, Fellow 1923

P. Martin Keller, M.D., Glendale, Calif., Elected Member 1929, Fellow 1931

Professor Herbert H. Waite, Lincoln, Nebr., Elected Member 1913, Fellow 1923

Andrew A. Cairns, M.D., Philadelphia, Pa., Elected Member 1914

Homer V. Knouse, Omaha, Nebr., Elected Member 1925

## TRAINING AND PERSONNEL

WITH the full support of the present administration of the Association, your Committee on Training and Personnel is undertaking an active program for the improvement of tenure and the further professionalizing of public health work. Through the use of this space, which has been made available to the committee by the Editor of the JOURNAL, we hope to keep you informed concerning the plans and activities of the committee and to give you news of interesting developments in the field. Constructive suggestions from fellows and members of the Association, sent to the committee at the New York office, will always be welcome.

The following statement is taken from a program of work recently approved by the committee, and presents the point of view with which the task is being approached. Specific plans and activities will be presented in subsequent issues.

### PRINCIPLES AND PROCEDURE

A. The activities of the Association must be based upon the fact that public health is a distinct profession.

The mere enumeration of specific public health activities such as epidemiology, vital statistics, public health laboratory procedures, water purification, and food sanitation, makes it obvious that both the administrator and the technical specialists in the health department use a body of knowledge not completely presented in the training for any of the professions most akin to public health. Further recognition is given to this fact, so far as medicine is concerned, in the creation of schools of public health quite separate from the medical schools in several universities. The fact that sanitary and public health engineering are distinct from

civil engineering is recognized by engineering schools which have established specific courses in this field. Similarly special programs of training have been set up for other specialists in public health. Until we can procure a recognition of the importance of special training (or experience) we cannot hope to secure permanency of tenure for the present workers or the appointment of trained workers when vacancies occur.

B. The first interest of the Association is the tenure of office for people in the service at present.

To be sure, we have in our various groups of public health workers at present people with widely diverse training and with varying degrees of efficiency. We must think of all situations and practicable training, not merely of the most important positions and of ideal training.

The people who are in service represent the profession as it exists today. Successful service is an evidence of at least some degree of proficiency. In every field, especially the field of public health administration, there will be difference of opinion as to what ideal training should be, but to start any program which would throw discredit upon present members of the profession who are giving satisfactory service would arouse discord within our own Association, confuse the general public, and retard the whole program.

It is only fair that the people who have gone into this field in the best way available to them and in the absence of specific guidance and who have become proficient through self-education and experience should have their tenure of office supported by the profession. We must not undervalue experience. Not all facts are learned in the classroom,

by any means. We must not, at this time, make a fetish of degrees, to such an extent that we draw sharp lines between present public health workers in service upon the basis of presence or absence of specific public health degrees.

If we are to succeed in improving public health personnel we must stand solidly behind the principle of continued tenure of office for every member of our Association now in professional work. We must begin where we are, start with minimum standards, and work through evolution rather than by revolution.

C. We must stand solidly for the principle that new appointments in public health positions should be made from the group of individuals who are trained in public health either by study or experience, or both.

We will try to keep the present personnel in office and eliminate displacements for political rather than professional reasons. We will try to induce public opinion and appointing authorities to insist upon replacements with properly trained people when vacancies occur in the natural course of events. In order to do this we will have to define some standards of training and experience and accumulate the list of individuals who meet these standards.

D. We should recognize experience as well as training in setting up these first standards.

As indicated above, we must not set up standards which disregard experience and give credit only to training secured through study for a particular public health degree.

## LETTER FROM GREAT BRITAIN

### VACCINATION—COMPULSORY OR VOLUNTARY?

OFF and on for a number of years, particularly since the effects of the "conscientious objection" clauses have made themselves felt, there has been talk among medical officers of health about the advisability of repealing the legislation relating to compulsory vaccination and placing the system upon a voluntary basis.

The transference of the administration of the laws dealing with the subject to the local health authorities following the abolition of the boards of guardians by the Local Government Act, and the issue of the now well known "Review of Certain Present Aspects of Smallpox Prevention in relation particularly to the Vaccination Acts, 1867-1907" by the Ministry of Health, rather brought things to a head. So much so, indeed, that the hunt appears to be fully up, with everybody

clamoring at once for an immediate abandonment of the compulsory system and the substitution of voluntarism.

In a report supporting this demand, prepared by the Medical Officer of Health of Brighton—where Sir Arthur Newsholme officiated for a number of years—and adopted and circulated by the local council, it is pointed out that under compulsion only about 50 per cent of the babies born are vaccinated and that, in any case, judging from the practical disappearance of a death rate from smallpox, it is a disease hardly worth worrying about.

As a further advantage it is claimed that, shorn of compulsion, vaccination would cost the country much less; a saving of about \$500,000 per annum, in fact, is promised. Probably it is this possibility that will influence local health bodies to join in a request to the Minister of Health to present a bill in Parliament for the repeal of the Vac-

cination Acts. The Society of Medical Officers of Health, who, with the Association of County Medical Officers of Health, propose to discuss the question fully, doubtless will consider this point also, in addition to many others of practical and administrative importance, before they make any recommendation to the Minister. That the Minister will decide off-hand to go for abolition, even with the Brighton and other reports in favor before him, is improbable.

The British system of government does not welcome wide and quick changes, and unless he has behind him a Royal Commission or at least a Departmental Committee, it is unlikely that the Minister will be prepared to suggest in the first instance anything more drastic than an amendment of certain provisions of the Acts or the issue of an order that will allow of simplification of the administrative procedure.

#### THE ORGANIZATION OF HEALTH EDUCATION

At the fourth annual conference of the Central Council for Health Education, held at the School of Hygiene and Tropical Medicine in London toward the end of November, health officers and representatives of health authorities, insurance committees and companies, and others interested in health education had the opportunity of conferring one with the other on the subject generally and hearing experts dealing with particular aspects and matters. Prominent among the speakers was Mr. Greenwood, Minister of Health in the previous administration, who, in pressing the claims of health education, claimed that it was "one of the most important factors in improving the level of public health in the country," and that the return obtained was out of all proportion to the expenditure upon it. The object of this latter pronouncement was to allow of an appeal to health authorities and others with funds

at their disposal, in their zeal for economy, to refrain from cutting down contributions to the Central Council.

As a fact, there are few organizations, so far as health propaganda and publicity are concerned, more deserving of support than the Central Council for Health Education. Formed by and at the instance of the Society of Medical Officers of Health, its own main object is economy: saving of trouble and expense to health officers and health authorities, insurance committees and approved societies (under the National Insurance Acts), insurance companies, etc., all of whom require guidance in connection with the choice of health educational organizations, material and what not.

Great Britain may not be unique in this respect, but one of the troubles, so far as health teaching is concerned, is the remarkable profusion of societies and associations, voluntary mainly, all longing to assist the official bodies in their propaganda with lecturers, leaflets, posters, cinema films, and so on. So many were these organizations and so much did they overlap, that the authorities were hard put to it to know the one from the other and the good from the bad.

The Central Council for Health Education, with the authority of the Society of Medical Officers of Health behind it, set about bringing order out of chaos; affording facilities for affiliation of the societies suitable for recognition: serving as a sign-post directing authorities, etc., to bodies appropriate for their particular purposes; advising with regard to literature and affixing their seal to suitable leaflets, pamphlets, films, etc.; keeping lists of lecturers; arranging for the loan of teaching material—films, etc.; communicating health articles to the press; and so forth.

Incidentally, one of the most useful and successful ventures of the Council is the publication of a propaganda

journal. Published under the title of *Better Health*, this journal enjoys a circulation of over 300,000 copies a month, and fulfils a most useful purpose. Another most useful function performed by the Council is in relation to the assistance given to insurance companies, committees and societies in the preparation of leaflets, and steadily greater and greater importance is coming to be attached to the seal of the Council upon health publications of various sorts. Of all the several contributions to the health service of the people by the Society of Medical Officers of Health there is none of greater value and moment than the Central Council for Health Education, and it is to be hoped that, in spite of the economy wave, funds sufficient to keep it afloat will be forthcoming.

#### THE PRINCE AND HOSPITAL OUT-PATIENTS

The Prince of Wales, whose interest in the work of hospitals in general, and those in London perhaps especially, is well known, has been greatly impressed by complaints made with regard to the overcrowding of out-patient (extern) departments and the length of time those seeking advice frequently are required to wait. With a view to seeing what can be done and whether in order to remedy these and other defects the departments in question should, apart from emergencies, be used only for the purposes of consultation with patients sent for second opinions or specialist treatments, his Royal Highness has

formed a special committee with directions to inquire.

Lieut.-Colonel Fremantle, who has been invited to serve upon this body, may be regarded as representing the public health service thereon since, though it is now some years since he resigned his appointment as County Medical Officer of Health of Hertfordshire to enter Parliament, he has continued to maintain close touch with the Society and his fellows, acting as Member of Council and attending meetings with as great regularity as his parliamentary duties will allow.

#### HONORARY FELLOWS—SOCIETY OF MEDICAL OFFICERS OF HEALTH

The nomination of Surgeon-General Hugh S. Cumming of the U. S. Public Health Service, and of Dr. F. F. Russell, Medical Director, Rockefeller Foundation, to the Honorary Fellowship of the Society of Medical Officers of Health of Great Britain has appealed to the many friends and admirers of these distinguished authorities on public health and preventive medicine on this side as eminently appropriate and has afforded very real gratification. Among others nominated by the Council of the Society on this occasion were Sir George Newman, Chief Medical Officer, Ministry of Health, England and Wales; Dr. Carl Humel, President, State Department of Health, Germany; and Professor Thorvald J. M. Madsen, Director, State Serum Institute, Copenhagen, Denmark.

CHARLES PORTER, M.D.

London

# PUBLIC HEALTH ADMINISTRATION

## BUSINESS AND OTHER STATISTICS IN HEALTH DEPARTMENT WORK BY MACHINE TABULATION

J. L. POMEROY, M. D., F. A. P. H. A.

*Los Angeles County Health Officer, Los Angeles, Calif.*

IT has become of tremendous importance in modern public health work to analyze much more intensely than was formerly necessary not only the results from a professional standpoint, but to combine cost statistics with the usual record of achievement. The pressing need of economical operation, the serious problem of meeting the criticisms of various investigating bodies, particularly those representing taxpayers, and the value of detailed data in the preparation of budgets, all justify the expenditure of considerable sums of money in securing adequate cost statistics. It appears that but little attention has been paid to this problem in public health work, and the system in vogue in the Los Angeles County Health Department may be of value to other similar departments throughout the United States.

The Los Angeles County Health Department resembles in many features that of a state department or a large incorporated city. The department performs work not only for rural areas but also for 35 incorporated cities. The total population served at the present time is approximately 800,000, about equally divided between incorporated cities and unincorporated area. The work of the incorporated cities is performed through business agreements between the governing bodies of the cities and the county, and it became necessary to have very accurate statistics both as to units of work and cost,

because of this contractual relationship. Needless to say, the application of these figures has been of enormous importance to the management in increasing efficiency and in revealing weaknesses. It is strongly recommended to health departments that the *Appraisal Form* of the American Public Health Association be used with a system of collecting costs and unit statistics of work.

### HOLLERITH TABULATING MACHINES

In searching throughout the business world for proper machinery, it was found that the electrical tabulating machine method through the assistance of Hollerith cards fitted our needs best. Public health work covers a field of different kinds of operations through which, however, there must be close correlation and coöperation. In its actual operation, there is an infinite variety of details to be considered. It is extremely difficult by hand tabulation to devise master sheets that are capable of being easily handled due to the enormous number of different facts on each sheet. The Hollerith card, however, is capable of handling just such a situation. It is possible on an 80-column card to have as many as 800 different classifications. Furthermore, since the major operations are automatic, the chances of error are reduced to the minimum. It is also possible to go back and take off quickly data which at any time may become very important with no added expense or technical diffi-

culty. With original records this operation would not only be expensive but require a long delay. It often happens in our work that we desire additional data from the past for purposes of comparison and the Hollerith card fulfils this situation. In other words, while the entire factual data from a record may be transferred to the Hollerith card, it is possible to use only a portion for current use and still all the material is in shape that it is readily available when needed.

#### THE CODE

In connection with the use of the Hollerith cards, it became necessary to devise a code of symbols and numbers used to represent functions, places, and things throughout the department. Coupled with this, there have been created a number of definitions which are of great value in the education of each employee in his daily work and his knowledge of the operation of the entire department. The system can be adapted to any health department because the functions can be re-arranged although the code numbers may remain the same. There would be some advantage for comparative purposes between departments if as far as possible the same code numbers became universal.

Our code is based on what is known as the Decimal System. In the County Health Department of Los Angeles County, there are 9 major bureaus which naturally then form a basis for the code. Thus the Bureau of Administration runs from 10 to 19; the Medical Service Bureau from 20 to 29; the Bureau of Maternal and Child Hygiene from 30 to 39; Bureau of Inspections 40-49; Bureau of Nursing 50-59; Bureau of Communicable Disease 60-69; Bureau of Laboratories 70-79; Local District Organization 80-89; Bureau of Medical Social Service 90-99.

In the actual use of the code the

whole numbers refer only to the work of the bureau chiefs, such as 10-20-30, etc. The next numbers, 11-21-31-41, etc., with their decimals refer to the functions and employees immediately working under the bureau chief and functioning throughout all districts. The local work performed throughout the districts and towns uses up the remainder of the digits from 2 to 9 with the usual decimal subdivisions. The arrangement of the code is such that unlimited expansion is possible, and whole numbers are left vacant here and there to pick up new functions as they develop.

#### OTHER CODES

In addition, each city and each employee has a code number. It is thus possible to pick out with the codes all the work performed in any city or town and also to segregate the cost for the entire department by personnel, nurses, inspectors, etc.

#### SYMBOLS

In connection with the code numbers, it was found expedient to use 2 full columns on the card, which permits the creation of 100 letter symbols to indicate the main kinds of work performed. This is precisely the same system as is used in the dial telephone where combinations of letters are used because of the difficulty of remembering numbers running over 4 or 5 digits. The letter code is translated in punching by the punch operator to numbers just as the operation of the telephone dial secures the same results through electrical magnetic operation in the telephone building. The letter system is really of considerable help not only as a memory system, but in segregating.

#### MANUAL

A carefully prepared manual of instructions giving the definitions of all terms used and their abbreviations,

with the different functions of the department, together with the entire code and samples of daily time sheets properly filled out, is furnished each employee.

#### DAILY TIME RECORDS

The character of the time sheets used differs according to the type of work performed, namely whether the worker uses an automobile or performs office work or other work confined to a building. Owing to the fact that the county government pays mileage, it is necessary to keep an absolutely accurate account of the day's trip, giving starting time, stopping time, and the address of each place visited, while the code takes care of the work performed and parallel, horizontal columns provide for the units of work.

#### CLINIC RECORDS

One of the most notable accomplishments has been the adaptation of this method to securing proper clinic records. It is a notorious fact that clinic statistics throughout the United States are relatively very inaccurate. An original and unique system has been built up in the department on clinic statistics and is being rapidly extended throughout the department. A code has been devised for tabulation in the clinics which obviates the necessity of bringing the original records into the office. This card serves as an index to each individual case of tuberculosis throughout the entire county, as well as a statistical card. The system of clinic records worked out in our department was described in "Measuring Out-Patient Service in Los Angeles County"—in *The Modern Hospital*, April, 1931, relative to the accumulation of proper totals on new patients, old patients, etc., concerning which there has been so much confusion throughout the United States in clinic statistics.

The number of cards punched and

sorted monthly is now 75,000. The number of employees in the department averages 455, including full-time and part-time persons. The total budget of the department last year was \$1,218,066.00. For an expenditure of 1.7 per cent of our total budget, we are in a position to secure accurate, detailed cost statistics of major operations of the department. Studies have already been made of costs of clinic visits by bureau and division, and costs of field work, which have resulted in many changes in management. For example, in relation to milk inspection, our studies have enabled us to cut down the cost of this work  $33\frac{1}{3}$  per cent. During the past year, with the aid of the Hollerith cost system the total amount expended by the department was decreased 5 per cent over the year previous, although the amount of floor space increased 31 per cent, the medical work in our clinics increased 33 per cent, and the communicable disease cases handled increased 45 per cent. Actually 5.1 cents less per capita was expended on salaries and maintenance for the year 1930 than in 1929, in spite of an enormous increase in work, due to the improved methods of management resulting from a better knowledge of details in the situation.

#### COMMITTEE ON STANDARDIZATION

In connection with the studies mentioned must be made of the work of the Committee on Standardization. This committee, created about 18 months ago, consists of a representative of the Bureau of Administration and of each of the major bureaus in the department, and considers all requests for new procedure throughout the entire department. Forms have been standardized, as well as the purchase of drugs and other supplies, and every effort made to apply modern business principles in bringing about economical operation. In a widely decentralized department

under the usual bureau system, such a committee correlates and investigates, and represents a fact finding buffer between the chief executive and the employee. It also permits the employee to participate in the management, arouses interest and secures better co-operation.

**Typhoid Fever in Salisbury**—In July, 1930, in Salisbury, Md., there occurred 80 cases of typhoid fever with 7 deaths. Fifty-seven of these cases were under 25 years of age. More females were attacked than males. The outbreak was traced to a typhoid carrier located on a farm producing milk for Dairy B. This dairy produced 3 types of raw milk, the first being put up in quarts, the second in pints and the third being a special baby milk with a colored cap. There were 532 households served by this dairy and in 265 instances milk bottled in quarts was used. In 50 of these 265 homes typhoid developed. In 203 homes, which took milk only in pints, no cases occurred and in 64 homes, taking only the baby milk, there were no cases. The carrier had had contact only with the milk sold in quarts. It was found that milk shakes purchased in drug stores were responsible for 6 cases. When the outbreak occurred a public clinic was established for immunization, at which 7,080 persons were treated and about 5,400 were immunized by private physicians. The population of Salisbury in 1930 was 11,081, while there were 31,304 inhabitants in the county.—S. H. Hurdle, Milk-Borne Epidemic of Typhoid Fever in Salisbury, Md., *J. Prev. Med.*, 5, 465 (Nov.), 1931.

**Goiter Prevention**—A comparison is made in the incidence of goiter in Cleveland and Detroit for the years 1914 and 1931. In the latter city following a survey made in the schools in 1924 a program for goiter prevention

was inaugurated by the Michigan State Health Department providing for the addition of iodine to table salt. In Cleveland opposition to such prophylaxis developed from physicians who emphasized the danger of hyperthyroidism. In Detroit in 1924, 36 per cent of the children examined were found to have goiters while in 1931 this had been reduced to 12 per cent and only 0.3 per cent had iodine deficiency goiters. In Cleveland in 1924, 34 per cent of the children examined had goiters, while in 1931 30 per cent were found to have goiters and 18 per cent suffered from iodine deficiency goiter. The reports of the Detroit Department of Health indicate that the incidence of goiter has decreased from 36 per cent in 1924 to 2.1 in 115,000 pupils examined in 1931. Also the number of toxic goiters has decreased in Detroit hospitals. The author concludes that Michigan has eliminated from her schools thousands of cases of feeble-mindedness which have in the past and would in the future result from endemic goiter.—O. P. Kimball, The Prevention of Goiter in Detroit and Cleveland, *J. A. M. A.*, 97: 1877 (Dec. 19), 1931.

**Illinois**—One of the new activities of the Illinois Department of Health, Division of Public Health Instruction, in 1930, was the construction of a series of scientific exhibits. This was a co-operative undertaking with the University of Illinois Medical College, which constructed the units, while the state division aided in planning and paid for the material and technical work.

Four units were constructed, one each dealing with pneumonia, typhoid, diphtheria, and tuberculosis. Each was built with the idea of presenting as fully as practicable the history, characteristics, importance, and means of control of these diseases. Pathological and normal specimens, charts, microscopic views, graphs and placards were pre-

pared for display, X-ray photographs were taken, and wax models were built. These elements were assembled into specially constructed booths for permanent exhibit purposes. They are to become the nucleus of a museum for medical students at the University, as well as forming the basis for general educational exhibits at the State Fair and for other appropriate occasions.—*Thirteenth Annual Report*, Dept. of Public Health, Illinois, 1930.

Providence, R. I.—An admirable set of health reports from Providence contains the records of the superintendent of health, the city registrar (including tables for 75 years), and the milk inspector, for the year 1930. These documents, from Dr. Charles V. Chapin, are of immense value to health administrators.

Model statistical tables, classified financial data, with comparisons for the previous year, and interesting descriptive text characterize the reports. The first step in the supervision of the health of infants is the distribution of prenatal letters to prospective mothers. During the year, 1,239 such letters were requested, 696 requests coming before the seventh month of pregnancy.

Six nurses supervise the children delivered by midwives (8 per cent of total) until they are 5 years old, making 14 calls on each well baby before it is 1 year of age, monthly calls during the second year, and 4 calls a year

thereafter. One nurse supervises the infants and young children in licensed boarding homes, and the infants of such unmarried mothers as are not under the nursing supervision of private agencies. One nursing visit is made to each infant delivered by a physician, provided the mother is not on the maternity service of the District Nursing Association or a ward patient at the Lying-In Hospital. Coöperating with the State Children's Bureau, nursing visits are made periodically to the licensed maternity homes and to day nurseries. The District Nursing Association employs on its children's service 21 staff nurses with 2 supervisors. During the year these nurses had under supervision 4,325 infants and 1,639 children, 1 to 5 years of age, inclusive. These nurses made 31,940 home visits to infants, 13,109 visits to preschool children, and 11,137 visits to 2,052 prospective mothers. Fourteen child welfare stations were maintained.

One of the features of the report of the superintendent of health is a series of tables for typhoid, diphtheria, and scarlet fever, 1884–1930, showing by years and months the cases and deaths. and by years the mortality and fatality rates from these diseases. For the past 16 years, separate data are also given for non-residents admitted to city hospitals. The city registrar's report of 127 pages contains a wealth of information for epidemiologists and health officers.

# LABORATORY

## A FURTHER NOTE ON THE DISAPPEARANCE OF BACTERIA APPLIED TO THE SKIN

JOHN F. NORTON, PH.D., AND MARGUERITE F. NOVY

*Department of Health, Detroit, Mich.*

THIS brief statement is intended to supplement results already published by the authors.<sup>1</sup> Arnold has suggested that the 10-minute interval between the application of bacteria to the skin and the first test for disappearance of the organisms does not give as striking results as when a shorter time interval is used. A series of 12 experiments was made by us, using *B. prodigiosus* as the test organism and the palmar surface of the hand as the test area. Samples were taken every minute and agar plate counts made ac-

cording to Arnold's technic. Table I gives the results.

The reduction in number of bacteria recovered is evident after 2 minutes and striking after 3 minutes. The same correlation between reduction of bacteria and apparent dryness of the skin surface, as previously reported, was observed in these tests. To determine the part the skin may have played in this reduction, tests were made in the following manner. A piece of brown wrapping paper was marked into uniform squares, sterilized; the surface

appearance of the test organism was more rapid on the surface of the paper than on the hand. There is no evidence in these experiments that the skin possesses any germicidal power.

Since the disappearance of pathogenic bacteria from the skin is of far more importance than that of the non-pathogen *B. prodigiosus*, two series of experiments were made to determine how the former group of bacteria would act. *S. hemolyticus* (a strain isolated from a case of erysipelas), *S. aureus*, and *B. typhosus* were used. In the first series, tests were made on washed hide and in the second, on brown wrapping paper according to the method described above. Comparisons should be made with the data already published for *B. prodigiosus*.<sup>2</sup> Tables III to VII give the results.

Again, reduction in the number of bacteria recovered as measured by the number of colonies appearing on agar plates corresponded to the time at which the surface appeared dry. The results with *B. typhosus* were almost identical with those obtained on washed hide when *B. prodigiosus* was used. The hemolytic streptococcus survived for a somewhat longer period than *B. typhosus*. The most resistant of the organisms tested was *S. aureus*. Even after the inoculated surface was apparently dry the reduction in numbers of *S. aureus* was relatively small as compared to *B. typhosus* and *B. prodigiosus*. A similar comparison can be made on the paper surface between these three organisms.

These experiments tend to confirm our previous conclusions that the skin possesses no inherent germicidal activity, and that the disappearance of certain bacteria from the surface of the skin is largely dependent on the removal of moisture. Pathogenic bacteria are known to vary in their resistance to desiccation. The results obtained in these experiments can be explained on the basis of this variation. The two sensitive species used in these tests lose their color when stained by Gram's method. The two more resistant organisms are Gram positive. Whether or not this relationship to the Gram stain would hold for other species is not known.

# CONNECTICUT OFFICIAL MILK SEDIMENT STANDARDS

FRIEND LEE MICKLE, F. A. P. H. A.

*Bureau of Laboratories, State Department of Health, Hartford, Conn.*

THE Milk Sediment Standards in use in Connecticut have recently been improved and made available for distribution. This is a photographic standard, being a marked improvement over preceding standards.

Studies made by the Bureau of Laboratories of the Connecticut State Department of Health in modifying and improving the test for visible dirt in milk and in developing a photographic Sediment Standard have been previ-

## CONNECTICUT OFFICIAL MILK SEDIMENT STANDARDS

1931

Connecticut Official Milk Sediment Standards  
This photographic reproduction of the standard is not to be used in lieu of standard in the actual grading of milk

ously reported.<sup>1,2,3,4</sup> Each laboratory in Connecticut making milk examinations has now been advised that the 1931 standards are ready for mailing. Each edition has found rather a wide use outside of Connecticut. A cut of the new standards is reproduced herewith.

The 1931 standards have several advantages over previous ones:

1. The photography is a marked improvement.

2. The diameter of the standard discs is the same as the discs to be graded.

3. The range of the standard now covers the entire range from Clean to Very Dirty on one photograph so that the one standard is applicable to both laboratory and field use for all samples of milk.

4. Both the "Cleanliness Ratings" from Clean to Very Dirty and the "Sediment Scores" are printed below the standard discs.

5. The "Cleanliness Ratings" are now more applicable to the correct grading of filtered, clarified or bottled milk.

6. The "Sediment Scores" are now design-

nated by whole numbers rather than by the small fractions that represented "milligrams per pint." Scores of 50 and below are "Clean" or "Acceptable"; scores of 75 and 100 are "Slightly Dirty" and "Dirty"; and scores of 125 or above are "Very Dirty."

Interested persons have been notified that the new 1931 standards can be purchased from the State Department of Health at Hartford, Conn., at a cost of \$1.00 each. The Director of Laboratories has requested that criticisms or comments following the use of these standards be made to him.

## VITAL STATISTICS

**New York State Death Rate Decreases. Nearly One-half in Four Decades—**In the course of the last forty years the general death rate in New York State was cut almost in two—from 21.4 per 1,000 population in 1890 to 11.7 in 1930. Had the death rate of 1890 prevailed last year, there would have been 270,489 deaths instead of the actual number, 147,424. In other words, the remarkable improvement in the public health represents a saving of almost 125,000 lives in the single year of 1930. The general death rate of New York City dropped 62 per cent between 1890 and 1930; upstate the rate decreased 28 per cent.

An analysis of the movement of mor-

talidity in the state in 1890-1930 according to age brings out the important fact that the reduction in the general death rate was due almost entirely to a decrease in mortality in the younger ages, under 45 years; there was but little improvement in middle life, while the death rate among older persons, over 60 years of age, has exhibited in recent years a slight upward trend.

The death rate among males was higher than among females at all ages. The total male death rate in 1930 exceeded the death rate among females by 18 per cent. In 1890 the excess mortality among males was somewhat less, 15 per cent. In 1930 the death rate among males was greater than that among females by 22 per cent in New

York City, and 13 per cent upstate.—New York State Dept. of Health, *Health News*, 8: 218 (Nov. 30), 1931.

**Annual Report of Surgeon General of Army**—Automobiles were the leading cause of death in the United States Army in 1930, according to the annual report of Surgeon General Robert U. Patterson. If it had not been for the material increase in the number of deaths from automobile accidents, the mortality rate for the year would have been the lowest on record. All but 11 of the 72 deaths from automobile accidents occurred in privately owned cars. Suicides, which, during 8 of the preceding 9 years, had led the list, were second, and tuberculosis was third, with drowning and cancer in fourth and fifth positions. The average daily strength of the army was 137,299. There were 50,910 enlistments in 1930 as compared with 61,898 in 1929. The annual hospital admission rate from all causes (608 per 1,000 men) was the lowest recorded in the history of the army. The most notable advance was in the control of communicable diseases, and especially of those transmitted through the gastrointestinal tract: typhoid, diarrhea and dysentery. The leading causes of admission were bronchitis, gonorrhea, acute tonsillitis, athletic exercises and chronic tonsillitis. The number of malarial fevers was reduced to less than 800 in each 100,000 men. During the year, 1,546,786 days were spent by the military personnel on sick report, as compared with 1,551,915 in 1929. The average daily noneffective rate from disease was 30.9 as compared with 31.3 in 1929 and 30.2 in 1928, and the leading causes were gonorrhea, tuberculosis, syphilis, athletic exercises and automobile accidents. The leading causes of disability were dementia praecox, tuberculosis, constitutional psychopathic state, mental deficiency and pes planus. The admission rate (47.7) for venereal

diseases was the lowest in the history of the army; this group of diseases caused 7.9 per cent of all admissions to hospitals and quarters, 16.3 per cent of the loss of time on account of sickness, 4.6 per cent of the discharges for disability, and about 2 per cent of the deaths. Since the inauguration of the campaign for the prevention of venereal disease in 1909, the army rate has been reduced 73 per cent. The rate for influenza was the lowest recorded since 1888.—*J. A. M. A.*, 97: 1719 (Dec. 5), 1931.

**Preliminary Report on Marriage and Divorce for the United States, 1930**—The Bureau of the Census announced that, according to the returns received, by the Department of Commerce, there were 1,128,180 marriages performed in the United States during the year 1930, as compared with 1,232,559 in 1929. These figures represent a decrease of 104,379 or 8.5 per cent. There was an increase of 4.2 per cent from 1928 to 1929. During the year 1930, there were 191,630 divorces granted in the United States, as compared with 201,468 in 1929, representing a decrease of 9,838 or 4.9 per cent. There were 4,333 marriages annulled in 1930, as compared with 4,408 in 1929. The estimated population of continental United States on July 1, 1930, was 123,191,000, and on July 1, 1929, 121,526,429. On the basis of these estimates, the number of marriages per 1,000 of the population was 9.2 in 1930, as against 10.1 in 1929; and the number of divorces per 1,000 of the population was 1.56 in 1930, as against 1.66 in 1929.

While the net decrease in the number of marriages performed in the country as a whole was 8.5 per cent, the relative change in the different states ranged from a decrease of 28.5 per cent in Texas to an increase of 29.5 per cent in New Mexico. (Only 9 states reported increases—Maine 3.9 per cent;

Nebraska five-tenths of one per cent; Virginia 1.3 per cent; Kentucky 2.1 per cent; Louisiana 1.0 per cent; Oklahoma 2.2 per cent; New Mexico 29.5 per cent; Arizona 4.2 per cent; and Nevada 6.4 per cent. Of those 9 states, 7 adjoin states in which recent changes in the marriage laws require from 3 to 5 days to elapse between the application for a marriage license and the issuance of the same. Virginia adjoins North Carolina where a law, effective July 1, 1929, applies to those under 21 years of age; Kentucky's increase is due in part to a change made in the laws of Tennessee, effective on the same date, but applicable to all parties; Louisiana, Oklahoma, and New Mexico adjoin the State of Texas where a law requiring physical examination as well became effective June 13, 1929; and Arizona and Nevada adjoin the State of California where the law became effective July 29, 1927. In the case of North Carolina and Tennessee, 5 days must elapse while California and Texas require 3 days.)

The rate of marriages per 1,000 of the population ranged from 4.6 in North Carolina and 4.7 in Delaware to 20.5 in New Mexico and 67.0 in Nevada. In general, the changes in the number of marriages per 1,000 of the population form a more satisfactory index of the trend with regard to marriage in the several states than do the actual number of marriages, because they take account of differences in the rate of increase in the general population.

In 1930, for the United States as a whole, 5.9 marriages for each divorce were reported, as against 6.1 in 1929. The District of Columbia and New York State, each having but one cause for absolute divorce, reported 57.5 and 24.5, respectively, while the rates in the other states ranged from 12.9 marriages to each divorce in Georgia to 2.3 marriages to each divorce in Nevada. The

changes in the various states as regards the number of divorces compared with the year 1929 ranged from a decrease of 19.1 per cent in the District of Columbia to an increase of 21.3 per cent in Delaware. Increased rates for divorces were reported by 9 other states, Maine, Massachusetts, Connecticut, Pennsylvania, Virginia, Arizona, Utah, Nevada and California. The ratio of divorces per 1,000 of the population in the individual states in 1929 ranged from 0.19 in the District of Columbia and 0.38 in New York to 3.22 in Oklahoma and 28.67 in Nevada.—*Prel. Report Marriage and Divorce for the U. S., 1930, Jan. 2, 1932.*

**Health Conditions in the United States, 1930**—In a report recently made to Congress, Surgeon General H. S. Cumming stated that reports of the prevalence of communicable diseases received by the Public Health Service from state health officers and preliminary reports of deaths from several sources indicate that the health record for the United States for the calendar year 1930 was exceptionally good.

The geographic distribution of smallpox in the United States is very irregular. Seven states—Kansas, Delaware, District of Columbia, Maine, Maryland, New Hampshire and Rhode Island—reported no cases of smallpox in 1930. The greatest prevalence of smallpox in that year was in South Dakota with 259 cases per 100,000 population. Indiana reported 164 cases of smallpox per 100,000 population and the State of Washington 152 cases per 100,000 population.

During the calendar year 1930 the incidence of influenza in the United States was unusually low. The death rate from influenza for the year 1930 was 18.7 per 100,000 population as compared with 54.6 per 100,000 population in 1929 and 42.1 in 1928. The fact that there was no general outbreak

of influenza during 1930 probably helped greatly in keeping the general death rate for the year low, as there is usually an increase in the number of deaths attributed to certain other diseases when influenza is prevalent.

Infantile paralysis was more prevalent during the calendar year 1930 than it was in 1928 or 1929. In the spring of 1930 the reports showed increased incidence of infantile paralysis on the Pacific Coast, and later considerable numbers of cases of the disease were reported in other parts of the country, especially in Louisiana, Oklahoma, and some of the North Central states. In the country as a whole, infantile paralysis reached its peak for the year about the first of October. An outbreak began in New York City soon after the close of the fiscal year. This outbreak later reached considerable proportions, the number of cases being considerably in excess of those reported for the preceding year.

The tuberculosis death rate for the calendar year 1930 was the lowest ever recorded by the Public Health Service. It was 68.5 deaths per 100,000 population as compared with 73.1 in 1929 and 76.4 in 1928. In 1900 the Bureau of the Census recorded a death rate from tuberculosis of 201.9 per 100,000 population. The difference between the tuberculosis death rates of 1900 and 1930 represents a saving of more than 160,000 lives in 1930 which would have been lost from tuberculosis in the United States if the 1900 rate had prevailed that year.

The prevalence of typhoid fever has been decreasing in the United States since comparable yearly statistics of cases and deaths have been available. During the calendar year 1930 a slight reaction was shown by the reports. The increase was reported during the last 6 months of 1930 and in some states at least it may have been influenced by the drought conditions which

resulted in pollution of water supplies or necessitated the taking of drinking water from new or unknown sources. The typhoid fever rates as computed from reports to the Public Health Service were as follows: 1930, 22 cases per 100,000 population; 1929, 19 cases; and 1928, 22.7 cases.

The case and death rates for diphtheria in 1930 were the lowest which the Public Health Service has ever recorded—54.2 cases and 4.9 deaths per 100,000 population. Ten years ago, 1920, the diphtheria case rate was 155 per 100,000 and the death rate was 15.3 per 100,000.

From 1924 to 1928, there was an increase in the prevalence of pellagra in the United States. In 1929 the reported incidence of the disease decreased somewhat, and there was a further decrease during the year 1930. During the first 6 months of 1931, however, 16,385 cases of pellagra were reported to the Public Health Service as compared with 13,359 cases reported during the first 6 months of the preceding year.

More than 1,450 cases of undulant fever were reported to the Public Health Service for the calendar year 1930. The disease has been recognized in every state of the Union.

Rocky Mountain spotted fever is not reportable in many of the states east of the Rocky Mountains. In 1930, 167 cases were reported from California, Colorado, Idaho, Montana, Nevada, Oregon, Washington and Wyoming. During the year workers of the Public Health Service identified, by laboratory and clinical studies, Rocky Mountain spotted fever, eastern type, in several states along the Atlantic seaboard. There is evidence to indicate its existence in this area at least since 1909. In 1931 cases were reported in the District of Columbia and Maryland.—U. S. P. H. S., *Health News*, H60.

# PUBLIC HEALTH ENGINEERING

## FACTORS IN THE ECONOMICS OF WASTE DISPOSAL

E. E. BUTTERFIELD

*Chairman of the Committee on Refuse Disposal and Street Cleaning,  
American Society of Municipal Engineers*

THE scope of this paper has been confined to several factors which I believe to be of fundamental importance for the economics of waste disposal, instead of a more pretentious attempt at a comprehensive outline of a combined system of the disposal of city refuse and sewage, in which the operating costs can be practically reduced to fixed charges and labor. A consideration of the combined system of waste disposal necessitates the introduction of the long and tedious computations of engineering thermodynamics as well as a familiarity with certain aspects of organic chemistry, which are not subjects of common parlance in waste disposal practice and literature. On the other hand, it is possible to bring into focus several outstanding features in the combined system of waste disposal and discuss them in more or less conventional terms.

### FUEL VALUE OF SEWAGE SLUDGE

#### *Combustible Gas from Putrefaction—*

The formation of combustible gas in the putrefaction of organic matter is well known to every bacteriologist who has used a fermentation tube and the gas formulas of Theobald Smith as an aid in the identification of species of gas-forming bacteria. The colon bacillus and the gas-bacillus of Welch, which are normal inhabitants of feces and sewage,

are active gas producers. Sewage grease is an important source of methane or marsh gas in the putrefaction of sewage sludge.

In the breaking down of protein, fat, and carbohydrate by animal and bacterial ferments, fatty acids are formed as intermediary products. The fermentative production of methane and carbon dioxide from the salts of fatty acids higher than acetic, including propionic, succinic and oleic, has been demonstrated experimentally by A. M. Buswell. Acetic acid is the end product of the beta-oxidation of straight chain fatty acids with an even number of carbon atoms.

In the oxidative deaminization of amino-acids from protein, carbon dioxide and ammonia are given off, and the resulting deaminized amino-acid is a fatty acid with one less carbon atom. One of the most widely known reactions in the fermentative production of methane and carbon dioxide from fatty acids is the bacterial hydrolysis of the calcium salt of acetic acid:

As a rule, the formation of methane from fatty acids does not exceed two molecules of methane for one molecule of carbon dioxide gas or one molecule of methane to one molecule of total carbon dioxide and carbonate. Methane is a relatively insoluble gas, whereas carbon dioxide is not only very soluble but

Presented at the Thirty-seventh Annual Convention of the American Society of Municipal Engineers at Pittsburgh, Pa., October 21, 1931.

it also combines readily with ammonia and other bases present in sewage to form carbonates, which accounts for the fact that the limiting value of the combustible gases in the gases from sludge putrefaction is about 85 per cent instead of 66.6 per cent. It has been stated that the average production of gas from sludge digestion amounts to 0.75 cu. ft. per person per day, with an average heating value of 750 B.t.u. per cu. ft. The average figures would indicate a production of 563 B.t.u. per person per day.

The fuel value of fresh sewage sludge varies from 4,000 to 7,500 B.t.u. per lb., dry basis; the values for a particular sludge depending upon the content of inert mineral matter and of adventitious grease, the former effecting a lowering of the heating value and the latter contributing largely to the higher fuel values of certain sludges. Taking 6,000 B.t.u. as an average for heating value of sludge, dry basis, and 0.15 lb. as the daily per capita contribution of recoverable sewage solids, there would be 900 B.t.u. contributed per person per day in the form of fresh and recoverable sewage solids.

Both of the figures, 563 B.t.u. from the gases of sludge digestion and 900 B.t.u. from fresh sludge, per person per day, are subject to errors in the law of averages, and the larger the numerical data, the smaller the error. It is well known that certain anaerobic, gas-forming organisms produce hydrogen in the course of putrefaction. Small quantities of hydrogen have been reported in the combustible gas arising from the putrefaction of sludge; the presence of hydrogen in these gases would raise the heating value of the gas above the theoretical limit of one-half of the heating value of fresh sewage solids. I have simply taken available data to indicate a loss of approximately one-half of the original heating value of fresh sewage solids when the same

solids are subjected to putrefactive fermentation with recovery of combustible gases, and why. A similar conclusion has been previously advanced by M. J. Blew from a study of the fuel values of fresh sludge and of the residues from sludge digestion.

**Mosquitoes Transported by Airplanes**—This paper briefly recites the growing public health interest in the possible importance of the transportation of mosquitoes by aircraft and the determination of the U. S. Public Health Service to answer the much propounded questions as to whether mosquitoes "are carried in airplanes, and, if so, to what extent, the distance of such transportation, the species of mosquitoes, and the types of planes on which they are carried."

Daily inspection of all airplanes arriving at the Miami, Fla., ports of the Pan American Airways System were made from July 23 to September 18, 1931. There were three types of airplanes: trimotor Fokker, Sikorsky Amphibian, and Commodore hydroplane—all cabin airliners.

Fokkers fly between Havana and Miami daily, between San Juan, P. R., and Miami three times a week, stopping at Santo Domingo, Port au Prince, Haiti, and Camaguey, Cuba, on the north-bound, 1-day trip. Sikorskys operate between San Salvador, Salvador, and Miami, stopping at Tela, Belize, Cozumel, and Havana (over-night). Commodores operate between Cristobal, C. Z., and Miami, stopping at Barranquilla, Colombia; Kingston, Jamaica (over-night), and Cienfuegos, Cuba.

From July 23 to September 12, there were 102 inspections made, and 29 mosquitoes captured, 1 male *Aedes aegypti* and 28 *Culex quinquefasciatus*. Representatives of the following species had been captured on the airplanes up to the time of the publication of the paper: *Aedes aegypti*, *Culex quinque-*

*fasciatus*, *Mansonia titillans*, *Aedes taeniorhynchus*, and *Anopheles albimanus*. The "Do-X" was also inspected and 4 mosquitoes were found aboard.

Very exact and conclusive experiments were conducted, wherein "laboratory-bred" mosquitoes were stained and placed aboard trimotor Fokker cabin planes at San Juan, P. R., just before leaving for Miami. *Aedes aegypti* (with a few *Culex quinquefasciatus*) were used. These, in cloth cages, were stained by spraying with an atomizer, using a 2 per cent watery solution of yellowish, water-soluble eosin, and about 20 c.c. of dilute stain for each cage of 30-40 mosquitoes.

The stained specimens were put aboard the plane on each of three successive trips, being liberated in all compartments just before the passengers got aboard and the plane took off. These planes leave early in the morning and arrive in Miami the afternoon of the same day, stopping at Santo Domingo, Port au Prince, and Camaguey, the time of stops aggregating more than an hour, and the flying time from San Juan to Miami being approximately 10 hours.

Of 40 mosquitoes (mostly *Aedes aegypti*) put aboard at San Juan on September 13, 13 were recovered from the plane on landing at Miami; 3 of 30 specimens placed aboard on September 16, and 6 of 30 placed aboard on September 18, making a total of 22 of the 100 stained specimens liberated on airplanes at San Juan which were recovered at Miami on the afternoons of the days of flights.

One of the investigators made the round-trip flight from Miami to San Juan and reported only 1 mosquito biting *en route*, and this at an altitude of approximately 3,000 feet. In identifying stained specimens, a solvent composed of glycerine 4 parts, absolute alcohol 4 parts, and ether 1 part was

used. Each mosquito was covered with a drop of the solvent and a tinting of the drop occurred if the specimen was stained.

A description of a power suction apparatus devised by the authors for capturing mosquitoes is given. Cuts showing types of airplanes, mechanical collecting device and staining procedure accompany the article.

The authors' conclusions are, briefly: (1) where airplanes may become heavily infested it may be expected that approximately one-fifth of the original number of *Aedes aegypti* will be carried for a distance of at least 1,250 miles. with repeated landings and opening of doors, hatches, etc.; (2) ordinarily, small numbers of mosquitoes are carried, but one infected mosquito might "start an epidemic," but "this mode of introduction of mosquito-borne disease is probably secondary in importance to the importation of infected man"; (3) "there is no obstacle to the efficient treatment of airplanes so as to destroy mosquitoes and avoid retardation of air traffic progress."—T. H. D. Griffiths and J. J. Griffiths, *Pub. Health Rep.*, 46, 47: 2775-2782 (Nov. 20), 1931.

**Sewage Reclamation Plant for Los Angeles**—In order to study sewage reclamation, the City of Los Angeles placed in operation on May 12, 1930, an experimental sewage treatment plant of 200,000 g.p.d. capacity. The purpose of the plant includes:

1. Development of a scheme of treatment which will not be a nuisance nor produce any odors, and will advance utilitarian values to a maximum.
2. Embodiment into one plant of all the best ideas as obtained from visiting other plants throughout the country and gleaned from accounts in the literature of foreign plants.
3. Utilization of mechanical equipment to the fullest possible extent.
4. Investigation into the treatment of industrial wastes.

5. Determination of basic design data for known process of treatment adapted to local conditions of climate, degree of treatment required, and character of sewage to be treated.

6. Demonstration of the degree of treatment required for each proposed scheme of reclamation.

7. Selection of a compact design consistent with simplifying operation.

8. Investigation of any harmful constituents in sewage which might interfere with various schemes of reclamation.

9. Reduction of operation costs to a safe minimum, with installation costs kept within reason.

10. Determination of installation and operation costs applicable to large plants, including labor, power, chemicals, depreciation, research, maintenance, miscellaneous items and contingency.

11. Studies on the recovery of power from gas, fertilizer from digested sludge, and the value of nitrogen in the activated sludge effluent.

12. Construction of a plant such that inspection by the public would gain their confidence and support.

There is a rather complete and interesting description of this undertaking, with sample record forms and photographs. The subject is discussed under the following headings: (1) Design of plant; (2) description of plant; (3) intake works; (4) sedimentation works; (5) aeration and sedimentation; (6) filtration of final effluent; (7) spreading grounds; (8) sludge disposal; (9) cost data; (10) what the plant is accomplishing.—R. F. Goudey, *Western Construction News*, 5, 20: 519-525 (Oct. 25), 1930. From *Pub. Health Eng. Abstr.*, Jan. 17, 1931. Abstr. A. L. Dopmeyer.

## FOOD AND NUTRITION

**The Fate of Carotene after Absorption in the Animal Organism—**Variations in the growth rate in response to carotene administration led to an investigation as to the effect on absorption of the character of the diet. Three types of basal diets were used, one, fat-free, another, low in fat, and the third, a fat containing diet.

Daily supplements with irradiated ergosterol and brewer's yeast were given and definite amounts of carotene administered after vitamin A deficiency became apparent. Carotene was administered either in ethyl laurate or palm oil and the excretion of the pigment was tested colorimetrically. As the absorption of carotene was measured by the character of the excreta, the colorimetric and spectroscopic examination of the fats extracted from the feces and from the caecum content was made.

The examination revealed that the yellow color of the fecal fats was entirely due to carotene but in the caecum content carotene accounted for approximately only 50 per cent of the color. The balance of the fat was similar to vitamin A.

Experiments to determine whether this was vitamin A derived from carotene by bacteriological action were negative in most cases, although probable evidence was found in two cases. The importance of the diet was indicated by the rats which when fed on a fat-free diet excreted 90 per cent of the pigment when administered in ethyl laurate. Absorption was better with carotene in palm oil and nearly complete when the basal diet contained 10 per cent of fat. On the basis of the evidence of the investigators that the liver plays an important rôle in the con-

version of carotene into vitamin A, an attempt was made to accomplish this with liver tissue *in vitro*, but without success. Further experiments by perfusing the livers of healthy, young cats with carotene solution were undertaken. In these cases the reserves of the cat in vitamin A had been depleted with appropriate feeding. No evidence of any conversion of carotene to vitamin A was obtained from any period up to 17¾ hours. The administration of carotene by mouth to the cats depleted of vitamin A showed no appearance of vitamin A in the liver or blood up to 40 hours. While a large proportion of carotene was unabsorbed, evidence indicated that the pigment entering the tissues was converted into other substances.—Bashir Ahmad, *Biochem. J.*, 25: 1195, 1931.

**Some Biochemical and Physiological Aspects of Copper in Animal Nutrition—**The increased importance attached to traces of certain metallic elements in food led to this work which was undertaken for further information as to the rôle of copper. While copper has been widely observed and recorded in plants no evidence has been offered as to its function in plant life.

No evidence was adduced by this work that copper bears a direct relation to chlorophyll. Analyses of the copper content of insects and marine animals are given showing an outstanding proportion of copper in the ink sac of the octopus. As no copper is found in the ink itself, the conclusion is reached that copper performs a catalytic function in the production of melanin. A study of the copper content of land animals, in-

cluding three human specimens, indicated that in spite of individual variations, the organs, as to their content of copper, ranged as follows: liver, kidney, heart, lungs, and spleen.

Copper was found in all tissues of the animal body including skin and hair. The copper content of the skin and of the livers of rats increased in relatively small degree compared with the additional copper in the diet.

A study was made on rats of hemoglobin building from inorganic iron, alone or with various supplements. Anemia was produced by cow's milk and the effects of the supplements measured by response in hemoglobin content of the blood. Rapid hemoglobin regeneration was found with copper supplements and rats became anemic when the iron supplements were stopped, notwithstanding a considerable store of iron in the liver, but when copper was fed hemoglobin regeneration followed, indicating the belief that copper feeding brought about utilization of the stored iron in the liver.

The mechanism of the copper reaction is explained on the basis that copper feeding increases the proportion of organic to total iron in the liver and that the change from inorganic to organic is a step in hemoglobin formation, achieved probably by a preliminary formation of a copper porphyrin and subsequent replacement of copper by iron.

The author found that the presence in the diet of over 100 times the normal amount of copper (as copper sulfate) had no detrimental effect on the growth, and normal young could be produced. The same amount as copper acetate or as verdigris was not toxic but no litters were produced by the animals receiving verdigris.—Ira James Cunningham, *Biochem. J.*, 25: 1267, 1931.

**Use of Ethylene (T-Gas) in the Destruction of Pests in the Presence of Foods**—From tests on nu-

merous foodstuffs it is established that the destruction of pests (in rooms or containers used for the storage of foodstuffs) by means of ethylene oxide in concentrations up to 320 g. per cu. m. has no adverse effect on the quality or flavor of the foods provided that the space treated is thoroughly aerated after treatment.—T. Sudendorf and E. Kröger, *Chem.-Ztg.*, 55: 550, 1931. Abstract, A. R. Powell, *J. S. C. I. Brit. Chem. Abstr.*, B, 50: 904 (Oct. 2), 1931.

**Vitamin C in the Orange and the Grapefruit**—This study of the relation between antiscorbutic potency and biological activity of the plant was conducted on Palestine oranges and grapefruit from British Honduras and from South Africa, and was continued through 2 seasons, using the same group of trees. The vitamin assay was conducted usually for 90 days and during the test oranges were stored at a temperature of about 15° and the juice expressed daily for the dosage. Chemical analyses of the oranges both seasons showed a range of acidity from 0.33 to 1.37 and the soluble solids citric acid or maturity ratio varied from 6.8 to 35.4. Practically no difference was revealed in the antiscorbutic potency of these oranges and the weight curves were normal.

A similar procedure was followed in the case of grapefruit from British Honduras which showed an acidity ranging from 0.58 to 1.18. No change in antiscorbutic potency during the time of these tests was noted. The same variety of grapefruit (Marsh) from South Africa was assayed. This showed a higher acid content than the same fruit from British Honduras. The vitamin potency, however, was of the same order in both cases. Another variety (Duncan) on one test only was found to be somewhat more active than other grapefruit and the vitamin C content of grapefruit was rather higher than that

of the Palestine oranges. The authors find no correlation between the soluble solids, acidity content, pH of the juice and its antiscorbutic potency.—Mary Forrest Bracewell and Sylvester Solomon Zilva, *Biochem. J.*, 25: 1081, 1931.

**Experiments on Nutrition. X. Comparative Vitamin B<sub>1</sub> Values of Foodstuffs. Cereals II**—The experiments here reported were made with pigeons. The food was made into pills of white flour and the test grain which was ground finely in a coffee mill. Later in the experiment 1 per cent of cod liver oil was included so the birds would not suffer from a shortage of fat-soluble vitamins. Fishmeal was used to supply protein and mineral salts. A series of tables are given showing the details of each cereal tested. The comparative vitamin B values of the cereals tested are as follows:

	Percentage amount in diet for maintenance	Comparative vitamin B value
Dried yeast	4	100
Marmite	6	67
Wheat germ ("bemax")	6-7	62
Middlings	10	40
Baker's yeast	12	33
Bran	20	20
Buckwheat	20	20
Millet	30	13
Oatmeal	35	11
Wheat	40	10
Barley	40	10
Malt	40	10
Rye	40	10
Dari	40	10
Brown rice	40	10

Robert Henry Aders Plimmer, William Henry Raymond and John Lowndes, *Biochem. J.*, 25: 691, 1931.

**The Latest Work on Alleged Injurious Effects from Food Prepared in Aluminum Utensils**—Professor Lehmann, in line with a former article (*Archiv für Hygiene und Bakteriologie*, Bd. 102, 1929, S. 349) calling attention to the worthlessness of the statements of Held and Betts, offers critical ob-

servations on the later articles described as "Aluminum Food Poisoning" by Betts and Held and other authors. He finds no proof of injurious effects on health of small amounts of aluminum.

The few records of sickness at the most can only lead one to believe that only a small number of people are made sick by the ingestion of small amounts of aluminum. There is still lacking definite proof that the symptoms are chiefly traceable to aluminum or that any considerable number of people possess a hypothetical idiosyncrasy toward aluminum.

The views of a greater number of authoritative individuals agree with this conclusion. The fact that isolated individuals might be injured by traces of aluminum does not offer a basis for opposition to the use of aluminum utensils and no legislation has so far taken cognizance of these very widely distributed cases of specific sensitivity to food.—Prof. Dr. K. B. Lehmann, *Arch. f. Hyg.*, Band 106, Heft 6 (Sept.), 1931.

**The Evidence of Aluminum and the Aluminum Content of Foods**—In preparation for the criticism of the work of Held and Betts published in *Archiv für Hygiene und Bakteriologie*, Bd. 102, 1929, S. 349, analytical methods for determination of small amounts were studied and continued during the past 2 years for improving the methods. These methods are described, and using these methods the aluminum content of a variety of natural animal and plant substances is given, including foods and certain animal organs, including human organs. Results of the author are also compared with the findings of other investigators.—Prof. Dr. K. B. Lehmann, *Arch. f. Hyg.*, Band 106, Heft 6 (Sept.), 1931.

# INDUSTRIAL HYGIENE

**Portable Motor-Driven Impinger Unit for Determination of Sulphur Dioxide**—This brief contribution describes an apparatus for the sampling of the atmosphere for sulphur dioxide gas. The essential collecting portion of the instrument consists of a modified Greenburg-Smith impinger apparatus through which the atmosphere is aspirated by means of a vacuum pump.

The novel form of the apparatus consists in the modified form of the impinger flask which in this case is approximately 25 cm. long and 10 cm. wide at the widest portion. The complete apparatus is mounted in a case 7" x 9" x 19½".

Normal sodium hydroxide is used as the collecting fluid. This is neutralized with 6 c.c. normal hydrochloric acid after which it is titrated with 0.001 normal iodide. A table is presented for the conversion of the c.c.'s of iodide solution used into c.c.'s of sulphur dioxide at various temperatures.—*J. Indust. Hyg.*, XIII, 10: 338-342 (Dec.), 1931.

L. G.

**The Production of Carbon Monoxide from Paint in Sealed Compartments**—In a series of laboratory as well as practical experiments conducted on battleships it was found that the air in hermetically sealed spaces contained traces of carbon monoxide. In general the amount of this gas was found to vary to some extent but usually was present to the extent of 0.3 per cent or less. It was concluded from these studies that the source of the carbon monoxide was the boiled linseed oil used in the making of the paint which coated the interior surfaces of the dead spaces aboard battleships. The presence of carbon monoxide in these stud-

ies was demonstrated by both chemical and biologic methods. The biologic tests consisted of animal experiments, while in some cases the Hartridge reversion spectroscope was used.—*J. Indust. Hyg.*, XIII, 10: 333-337 (Dec.), 1931.

L. G.

**Heat Cramps in Industry: Their Treatment and Prevention by Means of Sodium Chloride**—This very interesting contribution presents a review of the literature of heat cramps and describes a typical attack in much detail. The symptoms in addition to the cramps are chiefly an increase in temperature, pulse rate, blood pressure, an increased blood concentration, increased sweating, hyperpnea, increased metabolic rate, a falling in body weight, and certain vasomotor changes.

The author attributes to Dr. J. S. Haldane the suggestion that the cramps suffered by miners are due to salt loss.

In certain factories under the author's supervision, the use of salt began in 1926. At first it was used in small amounts, later the amount was increased to 10, and still later to 16 grains in the form of hard tablets. The salt must be readily available, and containers are described and pictured which are in use at the drinking fountains for the ready supply of the material.

The statistical evidence showing the elimination of heat cramp due to the ingestion of salt is not very satisfactory since the reporting of minor heat cramps is usually not completely carried out. In a general way the author points out that in certain large plants under his supervision the incidence of heat cramps has fallen very dramatically from the year 1928 to the year 1930, during

which time this salt technic was in use.

The most important factors in the production of heat cramps are high temperatures and high humidities coupled with low air motion; that is, factors which interfere with the heat loss from the body. Alcohol, inadequate sleep, inadequate food, and intercurrent disease predispose to heat cramps. Finally it is agreed that heat cramps are readily relieved by the administration of salt solution.—*J. Indust. Hyg.*, XIII, 10: 347-360 (Dec.), 1931. L. G.

**Report of the Division of Industrial Hygiene, Ontario, 1930**—It is felt that very limited application to industry has been made of the results of investigations regarding the reduction of general sickness in industry, and to optimum methods for performing common tasks such as the moving of loads by hand, etc. The medical supervision for the control of industrial diseases usually results in measures for the control of general sickness.

In investigations, 361 workmen were physically examined with the X-ray, practically all of some years' experience in their trades, covering iron moulders and grinders, porcelain workers, and cement workers. These presented 30 cases of silicosis and 8 cases of tuberculosis. The few cases among moulders arose only after 20 to 30 years' work in the trade. There were a few interesting cases of fibrosis among grinders exposed to artificial grindstone dust and 1 case with exposure to talc dust only.

Examinations of 176 workers from other sources included 100 claims for silicosis and 31 for lead poisoning, referred by the Workmen's Compensation Board. In the remainder of this group there were 10 cases of arsenic and 8 cases of chromium poisoning. In connection with these various cases hundreds of microscopical examinations were made, about 80 quantitative deter-

minations for lead and 40 for silica. Plant investigations likewise required analyses of paints, the dust content of air in granite cutting shops, lead contamination of fruits, poisoning from electric refrigerants, the efficiency of equipment for spray painting, carbon monoxide content of air, etc. Four deaths from gas in a sewage disposal plant proved to be due to hydrogen sulphide.

The records of sickness of 8,000 school children over a 2-year period are being studied in relation to ventilation, age, sex, and weather conditions on sickness rates and the relation, if any, of teachers' sensation of comfort and actual atmospheric conditions.

The division was represented at the International Silicosis Conference in August, 1930, at Johannesburg, South Africa.—J. G. Cunningham, Director, Division of Industrial Hygiene, Ontario, *Annual Report*, Dept. of Health, 1930, pp. 42-43. E. R. H.

**Chrome Poisoning with Manifestations of Sensitization**—Systemic chrome poisoning is seldom reported despite the fact that some of its compounds are markedly toxic. Chromium itself is non-toxic, but the oxides, acid, and alkaline chromates are directly poisonous as well as powerful irritants on account of their oxidizing properties.

The chief industrial uses of chromium are in dyeing, colored crayon and paper manufacture, inks, plating, and the graphic arts. The workers may be subjected to these compounds as liquids, dust, or vapors.

The symptoms of poisoning and researches on the toxicity of the compounds are described. Striking evidence of absorption from the skin occurs—12 fatalities being cited in the literature from the use of an ointment containing chrome. Acute renal blocking, muscular twitching, and febrile reactions due to infection or necrosis are

outstanding symptoms, but chrome workers suffer especially from dermatitis and rarely from chronic systemic poisoning.

The case here reported was that of an American, aged 25, who entered the hospital February 3, 1930, complaining of ulcers on the hands, difficult breathing and extreme tenderness of the muscles of the extremities. His history showed that he was a subject of hay fever and asthma previous to his employment in a plano-graphic printing establishment 8 months before, where he washed sheets of zinc which had been treated with ammonium bichromate. Skin lesions developed shortly after he began work, causing him to be transferred to another department, when these promptly cleared up. About 1 month before admission he returned to his original work and almost immediately skin eruptions developed. The clinical findings of the case are detailed, notably: marked redness, tenderness, minute vesicles, respiratory wheezes, leucocytosis but no eosinophilia, fever, and acute nephritis with glycosuria, but chromium was not demonstrated in the urine. The patch test applied to the forearm was positive.

The absorption of chrome in this case was probably exclusively through the skin, as there were no lesions in the nose or throat and no digestive symptoms.

Pearce and Sawyer succeeded in producing acute nephritis in dogs by the injection of serum from animals in which experimental chrome nephritis had previously been induced. It is evident in this case that the patient's serum was peculiar, since it contained some substance capable of causing a marked reaction in human controls when injected into the skin.

Despite the complicated picture presented by this case, it seems probable that it may be explained as due to general sensitization to chrome whereby a

comparatively mild exposure produced poisoning.—Adelaide Ross Smith, *J. A. M. A.*, 97: 95-98 (July 11), 1931.

E. R. H.

**The Dust Hazard in the Abrasive Industry: Third Study**—This study reviews the incidence of pulmonary tuberculosis among the employees of a factory devoted to the manufacture of synthetic grinding wheels. The dust in the workroom air is composed of aluminium oxide and silicon carbide.

In all there have been 42 cases of active pulmonary tuberculosis in the plant under consideration in the 13-year period from January, 1918, to December, 1930. The average number of employees during this period was 2,460. Twenty-seven of these cases occurred in persons not exposed to a dust hazard, while 13 occurred among persons exposed to dust. The time of onset varied from 1 year to 21 years. Excluding 4 cases following acute influenza, the proportion of cases occurring in dusty trades was 1½ times that occurring in non-dusty occupations. In spite of this the rate of pulmonary tuberculosis for the factory as a whole is a trifle above that reported for the City of Worcester, Mass., the location of the plant.

The only conclusion which the author desires to draw is—"it is not advisable for persons who have had pulmonary tuberculosis to work in a department in which large amounts of artificial abrasive or any other dust are present."—*J. Indust. Hyg.*, XIII, 10: 343-346 (Dec.), 1931.

L. G.

**The Silicosis Act in Quebec**—The Silicosis Act, 1931, came into force in Quebec, September 1, 1931. The Act requires every person employed in the cutting, polishing, or finishing of granite to have a certificate of fitness from a medical examiner appointed under the Act, which must be renewed annually.

The employer must furnish masks or

other safety devices as are approved by the Minister of Mines as a protection against silicosis and take such precautions as the Minister may prescribe.

An amendment to the Mining Act which also came into force on September 1, 1931, requires every worker employed underground in any mine, or applying for such work, to be examined for silicosis at least once in every 12 months by a medical officer appointed under the Workmen's Compensation Act. If the medical officer finds the worker to be free from tuberculosis of the respiratory organs, he shall deliver to him a certificate of fitness. A similar certificate is required of workers engaged in any ore or rock crushing operation at the surface of a mine except where the rock or ore is crushed in water, or a solution, and kept constantly moist.

The director of mines may exempt from these provisions any mine which does not contain silica in quantities likely to produce silicosis, or which for any sufficient reason he deems should be exempt. The Lieut.-Governor in Council may make regulations prescribing the nature of the medical examination and the form of the certificate. Workmen who are employed underground for less than 50 hours per calendar month are exempt from the provisions of the Act. Penalties are provided for contravention of the Act.—International Labour Office (League of Nations), *Indust. & Labour Inf.*, XXXIX, 13: 414 (Sept.), 1931.

E. R. H.

**Pneumonia in the Native Mine Workers of the Witwatersrand Goldfields**—This is a bacteriological and epidemiological study. In the mines, conditions of work differ from section to section and from shaft to shaft, while there is, in addition, a well recognized racial or tribal susceptibility to respiratory infections among the na-

tives, pneumonia in the recruits from the more tropical regions being greater than in those from South Africa. In 1929, the average monthly death rate from pneumonia, in a population of some 200,000 natives employed on mines, was 0.28 per 1,000. Nearly half of all deaths was due to diseases of the respiratory tract (other than silicosis and tuberculosis), and pneumonia was responsible for a third of the total mortality from disease.

Ceaseless effort in reducing pneumonia has proceeded since 1907 in the matter of improvements in mining and housing conditions and in the use of prophylactic pneumococcal vaccination, with a large measure of success so that the mortality rate from lobar pneumonia of 12 per 1,000 per annum in 1907 was only 3.36 in 1929, a reduction of about 75 per cent. Sir Almroth Wright and his coworkers began the prophylactic immunizations in 1911 and 1912, while Lister succeeded in classifying the types of pneumococcus responsible in 1914, and in introducing mass inoculation experiments in 1916. The incidence and mortality rates in lobar pneumonia were definitely and markedly reduced in the mines where these measures were used, including open workings as well as those underground. In 1917, mass inoculation of nearly all the native mine workers on the Witwatersrand was established as a routine.

(A considerable discussion on the bacteriological aspects and seasonal incidence of pneumonia, differences in local mining communities, and discussion of prophylaxis by vaccine follows, accompanied by tables and charts.)

It is concluded from all of the evidences gathered that a modified form of the one-time classical lobar pneumonia occurs frequently now. In this type of case there is a varied bacterial flora with or without the pneumococcus, and against this form the polyvalent pneumococcal vaccine is to a large extent

ineffective. The two peaks of high mortality occur in the winter and spring, apparently a different bacterial flora being present in each. From the constant change in the strain responsible there is need for periodically altering the bacterial elements of the prophylactic vaccine used against pneumonia, as well as to study the different strains in different localities.—David Ordman, *J. Med. Assn. of South Africa*, 5: 108–116 (Feb. 28), 1931. E. R. H.

(The above abstract should be compared with that which follows.)

In medical circles on the Rand there are conflicting views on the subject of pneumonia among mine workers. For years a system of prophylactic vaccination has been followed, but now it has been alleged to be of little value. Vaccination was almost universal on the Rand from 1917 to 1927, but today it is no longer so general, as many mine medical officers believe that vaccine prophylaxis is not a protection against the disease, although Sir Spencer Lister, who introduced the procedure, still does not hold this view. It is claimed that there are some discrepancies in diagnosing while no classification has been generally accepted.

The theory that pneumonia has changed its character on the Reef during the last 10 years is one that seems to be possible, but there is no evidence in favor of it. Mutability in the pneumococcus is of course known, but its extent and significance are little known.

An interesting fact is that although the incidence of the disease among mine natives appears to be high, the case mortality is decidedly low. This raises the suspicion that many cases of pneumonia are not really pneumonia but acute bronchitis. On the Rand the case mortality is 11; in Europe and America it is at least double that figure for patients of the same age as the average mine operative.

—Cape Town Letter, *J. A. M. A.*, 97, 16: 1164–1165 (Oct. 17), 1931.

E. R. H.

**Silicosis in South Africa**—This 44-page bulletin reprinted from the *Proceedings of the Transvaal Mine Medical Officers Association* held at Johannesburg, October 23, 1930, contains 3 papers by as many different authors, accompanied by 32 pages of half-tone plates.

The first paper by F. W. Simson, Department of Pathology, South African Institute for Medical Research, Johannesburg, is entitled "The Histo-Pathology of Silicosis," and considers the essential anatomy of the lungs, the lymphatic apparatus involved in silicosis, the relative changes as the result of dust inhalation, i.e., early reactive, the silicotic islet of non-infective types, and reactions to "infective silicosis."

The second paper is by A. Sutherland Strachan of the same department and is entitled "The Pathological Anatomy of Silicosis," the sub-headings being: Changes in the root glands, changes in the pleurae, changes in the lung substance, silicosis of "simple type," silicosis of the "infective type," and complications.

The third paper is by L. G. Irvine, Chairman of the Miners' Phthisis Medical Bureau, Johannesburg, and is entitled "The Correlation of the Pathology, Radiology and Symptomatology of Silicosis," the sub-headings being: Criteria of diagnosis, some preliminary considerations in the pathological diagnosis of silicosis, occupation of the lung by dust, terminology adopted under the Miners' Phthisis Act, silicosis—the "simple type," early stages, later stages, the "infective type," and tuberculosis with silicosis. Then follows a classification of radiographs adopted by the Medical Bureau and their interpretation including the blank to be used for reporting X-ray findings in various stages with cross-references to the accompanying plates, also a great deal of descriptive matter regarding the radiographs reproduced.

Dr. Irvine likewise indicates the radiographic technic employed at the Medical Bureau, the legal aspect, incidence, and prognosis in cases of silicosis, with some comparative data for European and native mine laborers.

E. R. H.

**Safety and Health in Tunnel and Caisson Work**—Two tables show the compensation statistics for tunnels, shafts, subways, and caissons, showing that caisson disease appears to be the most prominent and serious cause of accidents.

The general discussion covers in a code manner, supervision, and personnel, guarding machinery, fire protection, sanitation (wash houses, lockers, bathing and toilet facilities, drinking water, etc.), explosives, the matter of hand tools, electrical installations, haulage, and first aid; also the reporting and investigating of accidents and bulletin board services.

Among the safety features, four paragraphs are given to ventilation with significance standards as follows:

	Per cent
Carbon monoxide to be less than	.005
Carbon dioxide to be less than	1.00
Methane to be less than	.25
Hydrogen sulphide to be less than	.001
Oxygen to be more than	19.00

"Work in compressed air" considers the definition, cause and treatment of compressed air illness, while special stress is laid upon requirements for compressed air workers, their selections, health regulations, health suggestions, etc.

A section is devoted to compressed air equipment and other sections to air pressure, compression, decompression, hours of labor, communication, sanitation and ventilation, etc. A convenient

table shows relation between pressure and hours of work to be permitted. Seventeen illustrations accompany.—National Safety Council, Chicago, *Industrial Safety Series* No. Con.-2, 12 pp., 1931. E. R. H.

**Correspondence Committee on Industrial Hygiene, International Labour Office**—A number of members of this committee met at the headquarters in Geneva, July 30 to August 1, 1931, including representatives of some dozen countries. Proposals were submitted for the drafting of international relations to prevent anthrax infections in industries other than that of hides and skins, mainly referring to the handling of bones, hoofs, and horns.

The risks of lead poisoning in the process of enameling by powdered lead on cast iron were discussed, also the dangers of toxic solvents. The meeting recommended that all cases of poisoning occurring in the chemical industry be notified to the International Labour Office, which should hand on the information to interested parties. A program of research into the dangers of solvents was drawn up.

Every country was recommended to draw up regulations governing work in accumulator (storage battery) factories.

The conditions of work of married women were discussed and an approval was made to a proposal submitted by the Belgian Government to undertake an inquiry into this question in all of its aspects.

The meeting considered the conclusions of the International Silicosis Conference held at Johannesburg in 1930 and made suggestions regarding further research work on silicosis.—International Labour Office (League of Nations), *Indust. & Labour Inf.*, XXXIX, 6: 181 (Aug. 10), 1931. E. R. H.

## CHILD HYGIENE

THE most complete and unique report which has come to our attention recently is the annual report of the Los Angeles County Health Department for the fiscal year 1930-1931. It covers in detail all the work undertaken and accomplished, together with a complete financial statement including source of income and expenditures. The report is especially informative because it has clear-cut descriptions of each phase of the work. It contains excellent tables and charts which are easily read.

Dr. J. L. Pomeroy, the County Health Officer, states, "The year 1930-1931 will go down in history as one of the most healthful on record." The death rate was 10.4 per 1,000, compared with the rate for the United States as a whole of 11.3, and that for the State of California of 11.5.

The report reveals great progress in the control of many infectious diseases, especially those of childhood, and a marked reduction in deaths of infants under 1 year of age. It states the most outstanding achievement of the department has been the great reduction in deaths of children during the first year of life.

In spite of the fact that the Mexican babies make up 31 per cent of the total, the results of our health education work have been most successful. A series of charts is shown giving graphically this remarkable story. We do not believe any district in the country can show a more striking picture. The charts conclusively demonstrate the soundness of our program and the returns of the investment of taxpayers' money.

The infant mortality rate in Los Angeles County for 1930 was 46 per 1,000 as against

a state rate of 57 and a Los Angeles City rate of 62. Thus while the rate was 92 in Los Angeles County for 1916, and the state rate and City of Los Angeles rate was 73, due to more intensive and efficient work of the County Health Department we have reduced our rates lower than either Los Angeles City or the State of California. These reductions have been accomplished against the great obstacles of a large, scattered population, a very high Mexican population and the almost total absence of the many welfare, health and other social organizations so helpful in a large city.

The reduction effected shows for all races and all causes. Thus congenital malformations have been reduced nearly 6 per cent, as reflected by a marked reduction of deaths during the first month from 33 per 1,000 to 22 per 1,000. Gastrointestinal deaths have been reduced by over 50 per cent, falling from 22.4 to 10.0 per 1,000 from 1916 to 1930. Respiratory diseases dropped 40 per cent, falling from 15 to 9 per 1,000; communicable diseases declined from 14 to 2 per 1,000, a fall of about 600 per cent. All other causes fell from 10 to 8 per 1,000, a reduction of about 20 per cent. The grand total reduction has been 50 per cent from all causes.

The natural question to ask is, "How have such successful results been obtained?" This has been due largely to the excellent organization and efficient management of the Los Angeles County Health Department over 15 years. During that time the County Health Officer has developed gradually an organization which covers the health needs of the entire county in such a manner that each locality is given special attention. There are 12 district health officers coöperating with 35 cities and rural parts of the county.

The maternal and child health functions have been given special attention. Under the capable direction of Dr. Anna E. Rude this phase of the work has advanced remarkably during the last 3 or 4 years. Last year the Bureau

of Maternal and Child Hygiene "made up 15.8 per cent of the costs of salaries and mileage, 12.2 per cent of the costs of maintenance and operation, and about 11 per cent of the total per capita costs. A total of 19.1 cents per capita was expended on this function."

The total per capita expenditures for health services in the Los Angeles County Health Department for the fiscal year 1930-1931 was \$1,218,064 or \$1.72 per capita.

There are now 87 Child Hygiene Conferences throughout the county, at which mothers are free to bring their babies for advice to keep them well. Nearly 65 per cent of the mothers are reached at some time during the year. At these conferences the rules of hygiene for childhood are taught and demonstrated, special classes are held on nutrition and foods and health habit training, and the mothers are urged to keep the child under the observance of the family physician at the approach of the slightest illness. Babies are also vaccinated against diphtheria and smallpox. Nurses visit the homes to see that the rules are carried out, and to check up on sanitary conditions. Special work is done with the Mexican and Japanese, particularly adapted to their problems. Coördination is secured with the sanitary department so that local conditions affecting milk, water supply, foods and various other conditions affecting child life are corrected. Much literature in various languages is distributed, and lectures are given at Women's Clubs, P. T. A., and other meetings of women.

Sick babies are not taken care of by the Health Department, but are referred to private physicians and clinics. Undoubtedly our campaign for pure, wholesome milk has helped materially to lower the infant mortality, as well as our extremely favorable climate with its abundant sunshine.

It must be understood that the Child Hygiene Conferences are purely to give educational advice on hygiene and care to the mothers and not for treatment of sick children.

Of 65 families attending a Child Hygiene Conference, 43 had never consulted a child specialist before coming to the clinic. Thirty-four had no regular family physician. Thirty-two, or about 50 per cent, claimed

they could call a doctor if the child was sick. About 55 per cent claimed they absolutely could not afford to pay a private physician for advice on well babies. Only 15 per cent claimed they could afford to take their baby to a private physician if the Baby Welfare Work was discontinued.

From these results it is quite apparent that only one-half of the families have a regular physician, and only a small percentage are able to pay for well baby advice. Most would call a doctor when the baby is sick, but certainly the economic conditions have placed most persons at a serious disadvantage at present.

The maternal mortality death rate for Los Angeles County Health Department area has shown a steady reduction over a 4-year period, from 4.9 per 1,000 live births in 1927 to 3.6 in 1930.

Covering an 8-year period, from 1923 to 1930 inclusive, infant deaths due to congenital causes have been more than cut in half—a reduction of 56.7 per cent. The significance of these figures becomes apparent when it is remembered that "prenatal care" in the form of prenatal conferences had its inception into the County Health Department plan in 1923. There are 16 conferences in all. 1,252 cases or 11 per cent of total births were registered in these conferences this last year.

The annual figures indicate that 61.8 per cent of the total county births attend Child Hygiene Conferences. This is practically the same percentage as last year (61.9). . . . A total of 87 Child Hygiene Conferences have been conducted in 60 different localities in the county. This is an increase of 7 conferences over the previous year.

Work is also carried on for the pre-school child. The Bureau of Maternal and Child Hygiene has coöperated with the County Tuberculosis Association in conducting a Summer Health School for malnourished and undernourished children. This school had an intensive course in health habits, for 6 to 8 weeks, carried on in a school building. This plan reached the parents and helped to better home conditions. For 6 weeks each summer about 500 under par children received this training. The County Tuberculosis Association deserves great credit for supplementing the work of the Health Department. Besides helping toward salaries of some of the workers,

this organization is carrying on a nutrition program in the schools, supervising school cafeterias, doing health education work in clinics and schools, and assisting in publicity.

In connection with the County Tuberculosis Association we drew up a plan 2 years ago to focus our efforts on early diagnosis, and especially to work with the child. The program of prevention calls for—

1. Supervision of all contacts, or persons who have been associated with or lived with a person who has active tuberculosis
2. Tuberculin testing of all children who are contacts, or undernourished
3. X-ray examination of the chest of all positive reacting persons
4. Physical examination of the above
5. Adequate nutritional, health education, and focusing of all types of hygiene on the infected person to keep him well

**Children's Diseases**—Every American reader of the *British Journal of Diseases of Children* would do well to read 3 articles which appear in the July-September, 1931, issue:

1. Neurosis in Childhood—by I. M. Allen, M.D.N.Z., M.R.C.P., London
2. On the Incidence of Rheumatic Fever—Francis Bach, M.A., M.D., Oxon.
3. Thrombo-Phlebitis Migrans Complicating Scarlet Fever—J. B. Ellison, M.A., M.D., D.P.H.

Two papers bear directly upon problems with which we are struggling today in the public health field. That by Dr. Allen is based upon a careful study of 169 consecutive cases of neuroses in childhood which the author presumably has investigated. The clinical and the most important psychopathic and neuropathic features of the cases are discussed. These are divided into

1. The factors which make the child less able to face his environment and difficulties.
2. The factors which appear to excite the symptoms of a neurosis in the child at various ages.

The author feels that the cases in the first group are "built up in the majority of cases around the mother-child relationships." Treatment is considered under 3 main heads:

(a) *Prophylactic*—Adequate training of the mother of a first child in the principle of child welfare is essential. Correct training of the child from his earliest days in regular habits and adaptation to influences external to himself. . . .

(b) *Symptomatic*—The child is taught to control the particular symptoms which are causing him most trouble.

(c) *Psychological*—In every case it is necessary to readjust the individual attitude and the family, social, and school environment as far as possible, so that the child may be better prepared to deal with situations which arise later.

Dr. Bach, in the beginning of his article, states:

Included in the term "the rheumatic diseases" are a variety of conditions, the majority of which are ill defined, and of which our knowledge is limited. Rheumatic fever, juvenile rheumatism, rheumatic heart disease, and chorea are clinical manifestations of a specific disease.

*Rheumatismus infectiosus specificus* is an endemic, systemic disease whose definite cause is unknown. Rheumatic fever, according to Dr. Bach, is comparable in its clinical manifestations with syphilis and tuberculosis. He briefly describes its distribution in a number of countries, including Great Britain, Canada, the New England States, Scandinavian countries, and others. The recent study by Coburn in New York is mentioned. The importance of hereditary, sociological, and geographical factors is stressed. He concludes,

It is possible that the "rheumatic state" or diathesis is dependent on certain familial and environmental factors, such as have been mentioned, and that in these susceptible persons a certain organism, possibly *Streptococcus hemolyticus*, may set up a tissue reaction, which manifests itself as the clinical picture of

"rheumatismus infectiosus specificus" or rheumatic fever.

Dr. Ellison records two instructive cases in which inflammation of the veins appears as a complication of scarlet fever. In the "migrans" type of this disease the following criterions may be applied:

1. The lesions are disseminated in time and space, small lengths of superficial veins being usually first attacked.

2. Visceral phlebitis is to be expected, commonly in the veins of the lungs or abdominal viscera, more rarely in the heart or brain.

3. Although convalescence may be prolonged and relapses are to be anticipated, the prognosis is generally favorable.

## PUBLIC HEALTH NURSING

**A Joint Program Between a City Board of Health and a Visiting Nurse Association**—In planning for a broad community public health nursing program official and private agencies should work together. It is sound for them to have a joint public health nursing service, for the important thing is for the community to be adequately served by one group of public health nurses. This plan calls for a nurse administrator whose business it is to see that the staff nurses have technical nursing ability, that there is a staff education program for them, and that they receive special as well as general supervision, to insure high standards.

Here are some advantages of joint administration of public health nursing between official and unofficial agencies:

- It prevents duplication.
- It is more economical.
- It avoids intrusion of the home by a variety of workers.
- Patients, private physicians and nurses like it.

Health education is advanced because bedside care furnishes an unusual entree into the families' confidence.

The health officer can depend upon the same nurses to interpret the rules and regulations of the board of health.

In Denver a smallpox epidemic in 1922 made the City Department of Health realize the value of a visiting nurse association and in 1924 the board started to subsidize the Visiting Nurse

Association in an expansion of its communicable disease program. In 1928 the American Public Health Association, after making an appraisal of Denver's health activities, made the following recommendations:

That the nursing service of Denver be centralized in two main divisions:

(a) School and preschool nursing service (public and private schools). Private school work to be financed by the City Health Department but all school nursing to be under the supervision of one organization.

(b) Generalized public health nursing service (Health Department and Visiting Nurse Association).

That educational and preventive work be financed by the Health Department, bedside care financed by the Visiting Nurse Association.

That the Superintendent of Nurses be responsible to the Health Officer for Health Department work and to the Visiting Nurse Association Board for visiting nurse work.

That any new proposition relating to public health nursing should be considered by a group composed of representatives of the public health nursing organizations.

As a result of these recommendations, today the Denver visiting nurses visit every home in which a communicable disease occurs. Where nursing care is given, the cost is met by the Visiting Nurse Association. All educational work done by the nurses on these cases (1 visit to each minor, 2 to each major communicable disease) is financed by the health department.

The assistant superintendent of the Visiting Nurse Association makes a daily visit to the offices of the Department of Health and brings back all cases reported. She interprets the official and unofficial organizations to each other, and acts as a special supervisor of communicable disease work. In 1930 the Denver City and County Medical Society officially approved of this joint work.

Because of its charter the Denver Board of Education could not administer the health work in the private and parochial schools, so the Department of Health pays the Visiting Nurse Association to do this work.

All these joint plans entailed a great deal of work between the Visiting Nurse Association board and the Denver city officials. The Visiting Nurse Association came to lean so heavily on the manager of health for the city that he was asked to become a member of the Board of Directors for the Visiting Nurse Association.

This joint service in Denver is really just in its infancy, but since sound ground work has been laid the organization probably "would have little to fear from change of city administration, because, in the final analysis, the political forces crave to please the voters."—Kathryn Schulken, Health Department Nursing by a Visiting Nurse Association, *Pub. Health Nurs.*, XXIII, 12: 589-592 (Dec.). 1931.

The League of Nations Has an American Public Health Nurse on its Staff—Hazel Avis Goff, R.N., has been assigned to the Health Section of the League of Nations as adviser in matters affecting her profession which have to do with League projects in many quarters of the globe.

An early task Miss Goff has before her is the preparation of a public health survey to set before the League Health Section to serve as a guide for its ac-

tivities in this connection. Her general designation is field secretary for the League of Nations.

Christine Reiman, Executive Secretary of the Internal Council of Nurses, composed of the national nurse associations of 23 affiliated countries and the associate national representatives of 9 other countries, has her headquarters in Geneva. Until this time the Health Section of the League has consulted her freely about various phases of health education and schools of nursing. This has taken up a great deal of her time, and there is a growing need for field work. Miss Goff, who is a nurse well experienced in all phases of nursing, has been employed through the generosity of a philanthropic anonymous nurse in the United States.

The director of the American Red Cross Nursing Service chose Miss Goff from the long list of those who had seen foreign service under the Red Cross. She is a graduate of the Massachusetts General Hospital School of Nursing, Boston, and had had experience in several nursing schools in the United States when she was selected by the American Red Cross to direct the school of nursing the Red Cross was sponsoring in Sophia, Bulgaria. Here she was successful in founding a school which after a few years could be carried on under the direction of its graduates. After this she was field director on the nursing staff of the European office of the Rockefeller Foundation. She has recently received her B.S. degree in Public Health Nursing Administration from Teachers' College, Columbia University, New York.

Miss Goff will work directly under the Medical Director of the Health Section of the League and will be on an equal footing with her medical associates working under the director.

#### REFERENCES

**Do Nurses Know Mental Hygiene?**—Curiosity, keen powers of observation, and critical evaluation are three qualities vitally important in the work of the public health nurse. Yet her nursing school training seldom develops these because the routine rules of the hospital are apt to stultify her ability to plan and manage and make her dependent upon a set standard that does not require thinking. When she gets out into a public health district she is bewildered when she finds that each family and even each individual has different hygiene requirements. For one public health nurse who is wise in dealing with a family situation because she understands the underlying emotional implications, there are probably ten who "scold or dictate or mildly threaten, or apply some set formula, or agree with the patient because it is the easiest road to take, or give up the family in despair with the complaint that they are uncoöperative."

After being trained to take orders in the hospital, the freedom she finds in public health nursing makes the nurse's sense of importance go to her head. She uses on the patient the methods that have been used on her and orders him to do this and that "with a considerable air of omniscience and authority, without stooping to explain." In the hospital when the patient is in bed and unable to rebel this method may seem to work, but not in the home where the patient does not have to obey. Here, whatever is done has to have the approval of the family "from the dog up." "The visiting nurse who has not learned the technic of making friends with the watch-dog never even gets inside the door of many of her homes."

In the public health field the nurse has to learn that maladjusted personalities and emotional strains are often as potent in causing illness as typhoid, pneumonia, cardiac disease, arthritis, etc. A well known cardiac specialist

has said that 50 per cent of the problems in cardiacs is emotional, a great stomach specialist says that 50 per cent of the problems in gastroenteritis is emotional, and a specialist in internal medicine says that 40 per cent of the problems in medical patients is psychological, instead of physical.

There are many nurses in executive and supervisory positions who know the latest scientific methods of doing public health nursing "but they haven't learned the art of working with other people." They are now dealing with physicians, social workers, teachers, etc., whose coöperation they have to win by the "most delicate arts of understanding sympathy and persuasion," not by the authority of rank. Professional relationships get in a hopeless jam and they leave one position for another. Many of their difficulties are due to psychic injuries in childhood, but it may be that their hospital experience has put the final touch to their maladjustment.

A good psychiatric worker should be made a member of the faculty of every school of nursing. Her work could be divided between two fields, the faculty of the school and its students.

She could assist the faculty in the following ways:

- Help them to understand themselves and the student nurses as individuals.

- Help them learn how to lead. Most people learn to lead through training as much as through intuition.

- Help them to learn how to teach so as to awaken curiosity, stimulate thought and develop analysis and judgment.

- Help them to study the habits and attitudes which tend to cripple, and discover ways of compensating for them.

She could help student nurses in the following ways:

- Teach them to understand human nature, using the hospital for this purpose.

- Teach the relation of the mind to the body; of the emotions on the functioning of the body.

Increase their insight through individual consultations.

It may be that the majority of student nurses would profit more by a study of the more or less normal problems of personality than by the study of outright mental disease, though, of course, the nurses who wish to spe-

cialize in psychiatric nursing would need experience in the psychiatric hospital and lectures in psychiatric nursing. Perhaps nursing schools would do better to teach the majority of student nurses mental hygiene rather than psychiatry. —Elizabeth Fox, *The Nurse and Psychiatric Work*, *Mid-Monthly Surv.*, Dec., 1931, pp. 307-308.

## EDUCATION AND PUBLICITY\*

**Checking the Radio Audience—** Desiring to know to what extent, if any, the health department radio program is worth while, a survey was made in May, 1931, to ascertain if possible how many listeners existed. This survey was conducted by instructing health department nurses, in making regular calls in homes in their districts for any purpose whatsoever, to put a question as to whether the family living there was listening with more or less regularity to the health department program. These homes were taken just as they came in the course of health department business with no selection whatsoever; hence they were scattered over the whole city and represented all types of people.

This survey was repeated in the first week of November, 1931, in order to ascertain what changes, if any, had occurred in the status of the radio program. It will be seen that the apparent drop between May and November is to be explained by items two and three of the tabulations. In each survey about the same number of homes were visited. In May 76.4 per cent were found to have radios while in November radios were found in only 58.7 per cent of the homes, and many homes were found

without radio because of inability to buy batteries or tubes for old radio sets.

Since this survey represents only 6.9 per cent of the homes in Racine, it would seem reasonable to conclude that, even with liberal deduction for possible error, these listener ratios represent a worthwhile radio audience for our health message, and what is still more important, an audience that is growing.

	May	November
1. Number of homes at which nurses called	564	548
2. Homes without radio	133	226
3. Homes with radio	431	322
4. Homes in habit of listening to H. D. program	186	159
5. Homes not in habit of listening to H. D. program	245	163
6. Per cent of total homes listening	33.0	29.0
7. Per cent of total homes not listening	67.0	71.0
8. Per cent of homes with radio, listening	43.2	49.4
9. Per cent of homes with radio, not listening	56.8	50.6

The following preferences were expressed between various of our series of episodes:

Vacation series	26
Public health nursing	30
Scarlet fever and quarantine	26
Sanitation	15
Diphtheria prevention	32
Pre-school	20
Tuberculosis	12

—W. W. Bauer, M.D., Racine, Wis.

**Tuberculosis Doesn't "Just Happen"**—This title of a small folder is the keynote of the April, 1932, Early Diagnosis Campaign sponsored by tuberculosis associations. The carefully laid plans have included a variety of helps: printed matter, posters, lantern slides, motion pictures, electrotypes, and material to be adapted for state and local use.

Back of the popular material is a group of pamphlets for professional readers: health officer, social worker, public health nurse, and physician.

State associations will be the sources of supplies for the campaign. A list of what is being made available will be sent by the National Tuberculosis Association, 450 7th Ave., New York.

**Publicity by Physicians**—"Guided by the belief that the members of the medical profession," says the Medical Society of the County of New York and the New York Academy of Medicine, "and particularly members of these two organizations, are prompted by the desire to act in accordance with medical traditions and that code of ethics which, in its last analysis, has been laid down for the benefit of the public rather than the profession," the two bodies have issued *Principles Governing Contact of Physicians with the Public Through the Press, Lecture Platform, Lay Periodicals and Radio*, an 8-page pamphlet.

In considering the common avenues through which the profession and individual physicians may address the public, namely the press, the radio, the public platform and popular publications, we find three possible types of approach. These are publicity, propaganda, and public health education.

*Publicity* we witness in the medical world under two aspects. In one it gives due public notice of events which constitute legitimate news, such for example as the election of new officers in a medical organization; the opening of a new hospital; the award of a prize for distinction in medicine and the like. . . .

*Propaganda* has for its main objectives the arousing of public interest in supporting and

acting on health matters. In propaganda, emphasis is placed on some matter of public health interest and only incidentally upon the physicians connected with it. . . .

*Public Health Education* differs from publicity and propaganda by the nature of its content. A statement, for example, that measles is a much neglected and dangerous disease made by Dr. Jones may serve as a typical example of a public health education message. Such a statement should not give special prominence to its maker. . . .

### In broadcasting

The speaker's name may be given by the announcer without adorning and superlative references to his abilities or achievements. Dr. John Jones, Clinical Professor of Medicine at the X. Y. Z. University, will suffice as an introduction. Dr. John Jones, who is a practicing physician, should not be introduced as an internationally famous authority, etc. . . .

Health workers may well write for a copy to Medical Information Bureau, 2 East 103d St., New York. Use it as a guide in handling publicity when physicians serve the department or association.

**What Departments Told the Public**—Below are topics of recent press releases by state health departments. Do other departments issue mimeographed or printed releases to the newspapers?

Connecticut: "A Daily Food Plan Needed" (choice of food).

Detroit: "Prevalence of Certain Communicable Diseases"; "Trend of Infantile Death Rate in Detroit."

Iowa: "Ring-Worm"; "Lifeless Body" (carbon monoxide); "Needless Waste of Human Life" (homicides, accidents); "Christmas Seals."

Maryland: "Don't Broadcast Your Germs"; "Partnerships" (buyers of Christmas seals); "Take Care When You Skin or Handle the Meat of Wild Rabbits"; "Bad News and Good News" (diphtheria).

New York State: "How Can You Prove You Were Born?" (radio);

"Rickets" (radio); "What Is a Public Health Nurse?" (radio).

Oregon: "Pneumonia a Dangerous Contagious Disease"; "The Modern Health Officer"; "Child Hygiene."

U. S. Public Health Service: "Pelagra Preventive Value of Certain Canned Vegetables"; "Age and Sex Incidence of Influenza and Pneumonia"; "The Endocrines, Glands of Personality" (radio); "The Common Cold"; "Disease Reporting and Disease Prevention" (radio); "The Health of the School Child."

**Team-work in Public Health Education**—The development of "The Functions and Limitations of Government in Public Health Education" are traced by Dr. Allan J. McLaughlin up to and through the period when

Health officers gave up the idea that all public health work could be done by personnel on the payroll of the health department. It was obvious that the education of individuals in personal hygiene and the securing of their voluntary help in preventing disease involved the participation of many agencies, official and unofficial, outside the health department.

With the growth of unofficial voluntary agencies

The responsibility for the health of the people was still squarely placed upon the shoulders of the health officer, yet a large part of the work necessary to discharge his obligation had to be done by personnel not under his direct control.

Dr. McLaughlin raised the question: "What is public health education?"

When a health administrator essays to answer this question he is appalled by its magnitude. There are many narrow definitions which may be given by health workers in their own special field. There are drives for specific purposes which are public health education in its best sense; but public health education as a whole is so complex and consists of so many independent efforts that its scope and potentialities are tremendous.

Following a discussion of the partici-

pation of federal, state and local agencies, the schools and colleges, Dr. McLaughlin concludes:

The important thing for administrators to remember is that it matters little by whom the work is done, provided it is well done. Public health education has grown up in a haphazard manner, fostered by a score of agencies, official and unofficial. The time has arrived when the man charged with the responsibility for the health of all the people of a state—the State health officer—should take stock of what has been done and is being done by these diverse agencies. He should formulate with their help a comprehensive program to include all existing public health education activities and to expand the work or create new work so that the field may be as completely covered as possible.

All concerned with health education in or out of schools will wish to read the whole of this paper.—*Public Health Reports*, U. S. Public Health Service, Washington, Sept. 25, 1931. *Free*.

#### TIMELY TOPICS

"Why a Community Needs a Health Department," by John P. Koehler, M.D.—*Bulletin*, Milwaukee Health Dept., Nov., 1931.

"The New '18 Week Diet'"—*Everybody's Health* (Nov., 1931), St. Paul. "Adequate diet of meat and cereals and fruits and green vegetables and a quart of milk a day." *Sample free*.

A reminder of the wealth of material for press and house organ use which appears in the monthly issues of *Statistical Bulletin*, Metropolitan Life Ins. Co., New York. *Free*.

#### EXHIBITS

Making an exhibit eminently practical is described in *Quarterly Bulletin*, Frontier Nursing Service, Lexington, Ky., Autumn, 1931:

One of the nurses at the Red Bird Center had a most interesting health booth, the first of its kind to be held in that county. It stood out from the other exhibits by virtue

of its clean white walls, the nurse in her white uniform, and the bright colored health posters. Inside was an almost life-size sanitary dirt toilet as approved by the Kentucky State Board of Health, a model fly- and snake-proof baby-bed, and a model milk safe. Over each one was a printed notice giving the exact cost of lumber, nails, labor, etc., involved in the construction. There was also a baby scales with a sign, "Let us weigh your baby," which attracted many people, and a model layette on display. Chairs were provided outside for those who wished to rest, thus affording the nurse ample opportunity for giving advice and health instruction in addition to the printed literature which was, of course, on hand for those who read. . . . It might almost be said that the hero of the occasion was the sanitary toilet which caused intense interest and was the subject of an article in the *Manchester Guardian*, the local newspaper, the following day.

"State Fair Better Babies Demonstrations," by A. E. Schweitzer, M.D. *Bulletin*, Indiana State Board of Health. Oct., 1931. Describes what the State Board has been doing since 1920.

"Suggestions for a Food Exhibit," by D. Stackhouse. *Practical Home Economics*, New York. Dec., 1931. For a high school class.

An account of the 1931 Berlin housing exhibit says: "The German flair for arranging educational exhibits was shown at its best." Analyzed, is not that "flair" made up largely of belief in popular education, appreciation of the effectiveness of graphic displays, and a great willingness to invest thought, money and technical skill in their preparation?

#### HONORABLE MENTION

To American National Red Cross: For detailed table of contents in annual report.

To Division of Infant and Child Hygiene, Indiana State Board of Health: For table of contents (called "Index") in annual report.

To Quebec Provincial Bureau of Health: For annual report with table of contents and table des matières.

To Superintendent of Health, Provi-

dence: For annual report with table of contents.

#### FOR TEACHER—FOR PUBLIC

Mental Hygiene in the Class Room (44 pp.); Behavior Problems of School Children (20 pp.). National Committee for Mental Hygiene, 450 7th Ave., New York. 15 cents each. "That the teacher may realize that school is not simply a question of pushing children through the grades, but that it has all the diversity and importance of life itself, and that in helping children adjust to school she is helping them adjust to life."

From John Hancock Life Insurance Co., Boston (free):

Your Friend the Health Officer. 12 pp. For the public. Good copy for health officer to use. Good for private health workers to read.

Healthy Teeth. 12 pp. The minimum of what should be known.

#### CONTESTS

A contest for the best narrative report by a public health nurse is being conducted by *The Gleaner*, Bureau of Child Hygiene, Texas State Dept. of Health.

The Snappy Snapshot contest of *Public Health Nursing* (Nov. 11, 1931) resulted in two awards being given to "Weighing (Negro) Rural School Children" from Alabama, and "Houseboat Nursing" from West Virginia. The awards were based on "originality, interest and photoplay."

The Junior Red Cross seeks a new poster to be used in many countries. For details of the contest address Junior Red Cross, Washington, D. C., or national headquarters in your own country.

#### REPORTING

"Dumps," "Swine," "Garbage," and "Nuisances" are noted in the contents of an annual report. "Public Health Education" is not listed.

Two features of interpretation are found in the annual report of the American National Red Cross. Under the chief headings are from 2 to 6 lines, in italics, giving a brief outline of the scope of the service reported under that title. For example, under Home Hygiene and Care of the Sick:

Practical instruction in personal health and home hygiene, prevention of disease, infant and child care, simple procedures in home care of the sick and in emergencies, and community health.

In the financial statement of the Red Cross are explanatory phrases which make the items more clear and less formal than is frequently the case.

Quebec Provincial Bureau of Health, Montreal, has a few extra sets of its reports from 1922 which it will supply upon request.

"The Year in Review," in *Public Health News* (Sept.-Oct., 1931), New Jersey Dept. of Health, gives a readable account in 9 pages of the highlights of

the year. Frequent headings break the text and guide the reader.

Seven bright rose colored mimeographed sheets make up the annual report of Buffalo Tuberculosis Association, 708 Ellicott St. Plenty of center and side headings, with indentations, keep away any sense of heaviness. In making up the sheets a page of dispensary figures slipped in as the second page where it may discourage some readers from going further. A 3-page, yellow paper supplement reports on the medical work of the association. A photogravure page from *Buffalo Courier-Express* provides the picture element for this reporting project.

A mimeographed report can be accompanied by a page of pictures at low expense. Mounted on a sheet the size of the report copies can be reproduced by planagraph or similar process for about \$5.00 for 1,000 copies of letter-size sheet. The editor will supply addresses.

#### NATIONAL CHILDREN'S BUREAU ACTIVITIES OF ITALY

THE National Children's Bureau of Italy, an official body maintained mostly by public funds, spent, in the years 1927 to 1930 inclusive, more than 315,000,000 lire (\$16,569,000) on maternal and child welfare work. Of this sum 24,000,000 lire was used for teaching hygiene to the rural population. Nearly 400,000 expectant mothers and children were examined at the bureau's clinics; 1,800,000 children and 88,000 expectant mothers were examined and treated at its 59 traveling health centers, which so far have confined their activities to the rural districts of southern and central Italy. More than 165,000 children have been maintained by the bureau in sanitariums and other institutions for sick or defective children.

In addition to maintaining its own in-

stitutions, the bureau also subsidizes other institutions, public and private, and exercises supervision over them. Free lunch rooms for mothers and children and free maternity homes are also maintained. Financial aid to parents and to unmarried mothers is provided. Altogether the bureau extended aid to more than 766,000 persons, exclusive of the mothers and children examined at the traveling health centers.

During the years 1927 to 1930 more than 3,000 inspections were made of 2,800 institutions, resulting in general hygiene improvements. Under the auspices of the bureau a study was recently made of the diets in the various children's institutions, and standard dietaries were introduced into the institutions financially aided by the bureau. —*Maternità ed Infanzia*, Rome, Sept., 1931, p. 881.

## BOOKS AND REPORTS

**The History of Medicine**—By *Bernard Dawson, M.D.* London: *H. K. Lewis & Co., Ltd.*, 1931. 160 pp. Price, \$2.50.

This book is made up of lectures delivered to junior medical students of Adelaide University. In the brief space of some 160 pages, it gives a concise and accurate history of medicine from the earliest days down to the time of Lister and Pasteur. It is written in an interesting fashion and will undoubtedly fulfil its object of stimulating students to further studies along historical lines. We could wish that more space had been given to modern medicine, though we believe it wise to limit personal histories, at least, to those who have passed away.

There are a few errors of fact, but none of any great consequence have come to our attention. Altogether, we believe it to be the best book of its type which we have seen.

MAZÛCK P. RAVENEL

**Science in Action**—By *Edward R. Weidlein and William A. Hamor.* New York: *McGraw-Hill*, 1931. 310 pp. Price, \$3.00.

With a sub-title of "A Sketch of the Value of Scientific Research in American Industries," the publishers present an interesting and readable book telling the story of the growth of industrial research in the United States. The authors hail from the Mellon Institute of Industrial Research, Pittsburgh, Pa., and for 15 years have been popularizing science through lectures and articles.

The book attempts to explain scientific management of industries, including correct business administration and sound science in opposition to empiri-

cism, and to unfold something of the real magnitude of these present-day undertakings and their immense economic value. The discussion is divided into an historical or "groundwork" introduction, followed by 6 major parts, or divisions, respecting research itself, human welfare, technology, management and rationalization, methods and men.

The sources basic to industrial research are considered to be mathematics, physics, chemistry, geology, biology, psychology, economics and engineering. The spirit of such research is sincerely scientific and open-minded with the constant aim of discovering the truth and its application to human need. The latter is broadly discussed, including the relation to medicine, especially pharmacology, to labor, and to various international questions, with citation of the names of many corporations and individuals—so that a name index is provided in addition to a thoroughly complete subject index. In this connection those who are more particularly interested in the personnel of given research staffs and the exact research work carried on by each should consult, further, *Bulletin No. 81* of the National Research Council, by C. J. West and C. Hull—*Industrial Research Laboratories in the United States*, 4th ed., 1931.

An engaging philosophy of purpose and enthusiasm to urge on the accomplishments which must come to pass, pervades the present work. All interested in research in any way will enjoy it thoroughly, as it is fruitful of ideas and encouragement. Among other things stress is placed upon the excellence of equipment necessary to discover the many things now coming to

light which would have been impossible because of this lack in so recent a period even as that of Pasteur and Ehrlich. Today, research is needed to determine the medical possibilities alone of some 260,000 organic compounds.

Some statements occur which, of course, not all will agree with, such as "fatal issues now seldom occur" (in diabetes as the result of the discovery of insulin, p. 88), and the understatement that the vitamin "needs of the body are supplied largely by milk, butter, green vegetables and fruits" (p. 89).

Illustrations and a few tables accompany, while the general set-up of the work is all that good printing and publishing imply. EMERY R. HAYHURST

**Personal Hygiene Applied**—By Jesse Peirce Williams, M.D. (4th ed.) Philadelphia: Saunders, 1931. 520 pp. Price, \$2.25.

Since its appearance in 1922, this work has undergone numerous reprintings, and has now reached its fourth edition. This is evidence enough to show it has met with favor and has filled a need felt by teachers. While the present edition has been brought up to date, the chief new feature is the introduction of "Questions and Exercises" at the end of each chapter.

The book can be commended as one of the very best of its type.

MAZÛCK P. RAVENEL

**Common Pests. How to Control Some of the Pests That Affect Man's Health, Happiness and Welfare**—By Rennie W. Doane. Springfield: Thomas, 1931. 398 pp. Price, \$4.00.

This book, so written that it is understandable to the public as well as to physicians and health officers, is an account of common pests. It does not pretend to give anything original, but is a discussion in a single volume of the

more important groups of pests which directly or indirectly affect man and animal injuriously. Only the more common species of each group are treated. The discussions are brief, but clear, accurate, and sufficient for the general reader.

The illustrations are exceptionally good, well chosen, and many of them original. The reading of this book should do much to dispel the common dread in which spiders, scorpions, etc., are held by the public. We wish for it a wide circulation.

MAZÛCK P. RAVENEL

**A Text-Book of Oral Pathology—For Students and Practitioners of Dentistry**—By Russell W. Bunting, D.D.S. Philadelphia: Lea & Febiger, 1931. 495 pp. Price, \$7.00.

While there is not a chapter in this excellent book that is not of interest and does not contain material of value, two especially will appeal to the public health worker and are suitable for review in a journal on public health—those on dental caries and pyorrhea alveolaris. These are two vexed questions. Even the youngest of us can remember when the endameba buccalis was thought to be the cause of pyorrhea and emetin was given wholesale as an amebicide, until it was shown that the organism certainly had nothing to do with the disease and was found in the mouths of healthy people.

It may be said that in spite of the enormous amount of work which has been done upon it, it is still a puzzle. Two theories held have been that (1) it was constitutional, (2) that it was local. The author points out that the lesions are almost invariably accompanied by a local inflammatory process and that treatment of these as well as occlusal stresses often entirely relieve the condition and cures it. He inclines to the idea that both factors are involved and that the disease is the product of

both local and systemic disturbances. While discussing the various bacteriological findings, he apparently does not accord a great deal of importance to them as causative factors. He points out that caries and pyorrhea do not flourish in the same mouth, holding that the former is due to acid forming organisms present in the oral flora, while in the other, proteolytic types of microorganisms find a habitat in the soft tissue about the teeth, producing their characteristic effects. He leans strongly to the idea that caries is due to the acidophilus and has produced the disease, apparently typical, both in the test tube and in the living being. In more than 2,000 cases he has found the acidophilus practically always, while it was absent from healthy mouths. Consequently, he regards caries as an infective disease. He recognizes the difficulty of explaining why these aciduric processes prevail in one mouth and not another.

He also recognizes the necessity of good food during the formative period, but does not go so far as many of those who are enthusiastic over the effect of the diet.

The book is abundantly and excellently illustrated. Certain chapters have been written by specialists, though the bulk of the book is due to the author. Altogether, it is one of the most thoughtful, exact and informative books on the subject which it has been our fortune to read. The printing and make-up are excellent though unfortunately it is on very heavy paper.

MAZŮCK P. RAVENEL

#### Nineteenth Annual Report of the International Association of Dairy and Milk Inspectors.

This, the 19th Annual Report of the association, includes the constitution, by-laws, program of the 19th Annual Convention, reports of committees, and papers read at the convention which

was held in Cleveland, O., October 22-24, 1930.

The many important and interesting papers read included "Those on bacteriological and laboratory studies and procedure plant studies, including time and temperature, inspection of plants, cleaning and sterilization of equipment, flavors in milk, milk control from farm to table, coöperation problems between inspectors and plants and opportunities in the dairy industry. Other papers included a survey of New York State milk and cream supply, one on undulant fever, and a report on such activities of the International Association of Milk Dealers as would be of interest to this association. Every paper had something to offer to the milk industry in general and the report is of particular interest to every dairy and milk inspector as well as public health official.

V. B. L.

*Annals of the Pickett-Thomson Research Laboratory. Volume VII. The Pathogenic Streptococci. The Rôle of Streptococci in Erysipelas, Skin Diseases and Measles—Baltimore: Williams & Wilkins, 1931. Price, \$10.00.*

The style of the three monographs in this volume is essentially the same as that of the preceding five on the streptococci. The aim is to present a complete survey of researches recorded in the literature, to which the authors have added their own findings as to the value of Crowe's medium in the differentiation of various species of streptococci, together with an extensive series of microphotographs. Since variation in the moisture content, etc., of Crowe's medium causes variation in colony form, the difficulty with this method is apparent.

The monographs are devoted to the rôle of streptococci in erysipelas, skin diseases and measles. *S. erysipelatis* is recognizable as a distinct species of he-

molytic streptococcus by means of an iodine test of colonies grown on Crowe's medium, sugar fermentation tests, serological and bacteriophage tests. It is thus the specific infectious agent in erysipelas. The confusion between *S. pyogenes* and *S. erysipelatis* as the causative agent may arise because of its ubiquity, the fact of a secondary infection in the disease, as well as the possibility that there are varieties of streptococci which lie intermediate between the two.

The survey of the researches on the etiology of skin diseases reveals that in many cases the problems remain unsolved. This is probably due, at least in part, to the difficulty in cultural methods. The chapter on selective methods of cultivating streptococci from the skin should assist in further researches in this field.

The authors summarize the results of researches on the etiology of measles as follows: "It would appear that the cause of measles has not yet been discovered, and it seems likely that the disease is caused by an invisible non-cultivable filter-passing virus" (p. 384). They, however, state that further researches are necessary before the organism of Caronia, a specific streptococcus, and the pleomorphic organism described by themselves can be disregarded. Their own researches are presented and furnish material for interesting speculation.

To each monograph is appended the bibliography and photographs of organisms and colonies.

This volume is another valuable asset to all persons interested particularly in the research aspects of the streptococci. Excellent organization of material renders the use of the volume easy. The index of each monograph is complete. The volume abounds both in facts and problems still unsolved in all phases—bacteriological, immunological, epidemiological, etc.—of the diseases discussed.

ESTHER W. STEARN

*Confessio Medici*—By Stephen Paget, F.R.C.S. New York: Macmillan, 1931. Price, \$2.00.

This delightful series of essays needs neither criticism nor commendation. It has been before the profession and public for nearly a generation, and is familiar to all sincere readers. To the older members of the profession, it needs no introduction, but we wish to commend it especially to those who have entered the profession in the last few years or who will enter it in the future.

The publishers have put it out in excellent style on mat paper and in clear type. There is no one who cannot get enjoyment and profit by reading these essays.

MAZÏCK P. RAVENEL

*The Lungs: and the Early Stages of Tuberculosis*—By Lawrason Brown, M.D., and Fred H. Heise, M.D. New York: Appleton, 1931. 140 pp. Price, \$1.50.

The volume is the latest addition to the Appleton Popular Health Books. It is comprehensive and compact, presenting in 140 pages much valuable information regarding the latest conception of the cause, prevalence, detection, prevention and treatment of tuberculosis.

The first chapter describes the anatomy and physiology of the lungs. The style is in some parts a trifle labored, due no doubt to the authors' desire to make certain necessarily technical information comprehensible to the lay reader. The book should number, among its most interested readers, nurses, students and tuberculosis patients. All lay readers will find it a valuable contribution to a subject of vital importance in this day of preventive medicine. The book contains a very good index. The prominent tuberculosis specialists who collaborated on the work need no introduction.

L. O'LEARY

**The Family in the Present Social Order**—By *Ruth Lindquist*. *Written and published with the coöperation of the American Home Economics Association*. Chapel Hill: University of North Carolina Press, 1931. 241 pp. Price, \$2.50.

The factual data from which the observations and conclusions found in this book were made, were obtained through the questionnaire method. Information was obtained from the alumnae of two professional fraternities with the assistance of some of their close friends. An effort was made to secure, as far as possible, information of the more pertinent conditions that directly or indirectly affect the health and happiness of the home. This approach to an understanding of the problems presented by the family has considerable merit, for it discloses, to a very suggestive if not convincing degree, effects, not only of the material aspects such as income, living conditions, neighborhood and the like, but also of the spiritual or mental factors such as different philosophies of life, the effects of different social backgrounds, temperament, religious practice, and the like. The author has been very careful in her interpretations so that her conclusions are never extravagant.

There is an appreciation that the material collected is not entirely complete or far-reaching enough to explain all the conditions that tend to mould the life of the individual family. As the questionnaires were sent only to women the problems that the husband and father contributes to and those which he is also called upon to solve are necessarily not included. The problems more characteristic of the family belonging to a lower economic strata are naturally not brought to light, as a large per cent of those coöperating in this study had more than a high school education. Only 1.2 per cent had an income of less than \$1,800 per year.

This study is in line with the general trend of thought today, that education, if its purpose is to prepare individuals for life, must include, in addition to the giving of facts, an understanding of oneself and of others, with some technic of making the necessary social and personal adjustments. There is abundant proof in the study that preparation for marriage is evidently a necessity.

This little volume has considerable merit and can be read with a great deal of profit by those contemplating marriage and wishing to have some knowledge and insight into the sphere of life they are contemplating entering; it also can be helpful to the professional worker who in any way comes in contact with family life and who is in a position to advise or otherwise help.

The book, itself, is very well written so that the reader finds himself taken along page after page due to the importance and challenge of the material and also because of the excellent way in which it is presented. There are two appendices. Appendix I is a statistical presentation of the three special groups in the study on the basis of the types of education and training the women possessed. Appendix II contains questionnaires. There is a selected bibliography that is very valuable.

FRANK J. O'BRIEN

**School Nursing: A Contribution to Health Education**—By *Mary Ella Chayer, R.N., B.S.* Introduction by *Katharine Tucker, R.N.* New York: Putnam, 1931. 292 pp. Price, \$2.50.

At last we have a book which orients the public health nurse in relation to health education. Miss Chayer's combined training and experience qualify her to deal with this controversial subject. She writes from the standpoint of an educator as well as a public health nurse. The book is, therefore, specific as well as comprehensive; practical as well as philosophical. It has been ap-

parent for some time that the school nurse makes a distinct contribution to health education, and the author of this excellent volume tells us just why, when, and how.

Two types of school nursing seem to be emerging—the health service type, which deals largely with the control of contagion and the correction of defects; and the health education type, which aims at the fullest development of the personality through supervision of the emotional and social aspects of health as well as of the physical. In the latter type, health service is solely a means to the end of health education.

The entire chapter on Principles of Education as Applied to the School Nurse is particularly timely. The individual needs of the school child are given due consideration, and the means of reaching the child through parental education and home nursing are discussed. Another chapter, which should prove helpful to school nurses, is on Relationships.

It is very encouraging to note the emphasis placed upon the proper training of the nurse for health education. The author contends that only nurses with adequate training in both the educational and public health fields should attempt to qualify as health educators or health coördinators.

The book is well printed, illustrated, and indexed, and contains a good working bibliography of books, pamphlets, and magazine articles.

RICHARD A. BOLT

**Preparation of Scientific and Technical Papers—By Sam F. Trelease and Emma Serepta Yule. Baltimore: Williams & Wilkins, 1930. 113 pp. Price. \$1.50.**

This is a reprint of the second edition. The pronounced success of the book has proved its value, and there is little to criticize.

We cannot quite understand the incompleteness of the lists of journals with abbreviations. Too many have

been given to serve simply as examples, and not enough to cover the ground. For example, under Medicine, neither the *British Medical Journal* nor the *Lancet* is mentioned. Under Hygiene, the *American Journal of Public Health*, which we believe to be the oldest in existence, is not found. Many other omissions of journals which should be useful to scientific writers are noticed.

If it were not for the serious nature of the entire book, we would suspect the authors of a sly dig at scientific writers. On page 27, the specimen heading for a thesis given is "Cultivation of Coconuts," which might not be a bad name for this work. The printing and make-up are excellent, and it is a distinct addition to the armamentarium of both writers and editors.

MAZÏCK P. RAVENEL

**Nutrition and Physical Fitness—By L. Jean Bogert, Ph.D. Philadelphia: Saunders, 1931. 540 pp. Price, \$3.00.**

This small book, discussing the nutritional needs of the body, chemistry of nutrition, planning of meals, and diets for special conditions, gives a large amount of useful information. A commendable portion of the chapter on fruits and vegetables describes the value of base forming foods; and that on the vitamins and mineral salts is well illustrated from articles by authorities on nutritional deficiencies. An outstanding feature is the discussion of meal planning, food economics, the effects of cooking, and fads and fallacies about food. The significance and treatment of overweight are given commendable attention, but very little is written about other phases of physical unfitness. An appendix contains some useful tables. The text is clear, concise, and well illustrated. The book should be of special interest to the laity, dietitians, nurses, and medical students.

FRANCIS L. BURNETT

**Nucleic Acids**—By *P. A. Levene and Lawrence W. Bass*. New York: *Chemical Catalog Co.*, 1931. 337 pp. Price, \$4.50.

The interest that biologists have in the nucleic acids is obvious. Few of them, however, have the necessary training to make laboratory studies of these fundamental substances. On the biochemist and the organic chemist (if such a distinction is allowable) must fall the labor of investigation. The authors have given an unusually readable and logical account of the chemistry of these extremely complex organic compounds characterized as esters of phosphoric acid with an organic radicle "consisting of a sugar and a nitrogenous component which is a cyclic derivative of urea."

After a discussion of the sugars the

reader is introduced to the imidines and imido esters, to the pyrimidines, the purine bases, the nucleosides, the nucleotides, and finally to the nucleic acids.

Even if the biologist has forgotten most of the complicated organic formulas which he might have known at one time, the book is well worth reading because of the impression that is left, although the formulas may rapidly disappear from the conscious mind.

The bibliographic references are extremely numerous so that those desiring to go further into the subjects discussed will have no difficulty in locating original material. Brief mention is made of the studies on nucleic acids of the tubercle bacillus. The authors have made a notable contribution.

JOHN F. NORTON

## BOOKS RECEIVED

**CONFESSIO MEDICI**. By Stephen Paget. New York: Macmillan, 1931. 158 pp. Price, \$2.00.

**THE DOCTOR EXPLAINS**. By Ralph H. Major. New York: Knopf, 1931. 277 pp. Price, \$3.50.

**EXAMINATION OF WATER**. 6th ed. By William P. Mason and Arthur M. Buswell. New York: Wiley, 1931. 224 pp. Price, \$3.00.

**INDUSTRIAL HYGIENE FOR ENGINEERS AND MANAGERS**. By Carey P. McCord. New York: Harper, 1931. 336 pp. Price, \$5.00.

**MEDICINE IN VIRGINIA IN THE EIGHTEENTH CENTURY**. By Wyndham B. Blanton. Richmond: Garrett & Massie, 1931. 449 pp. Price, \$7.50.

**OFFICIAL AND TENTATIVE METHODS OF ANALYSIS OF THE ASSOCIATION OF OFFICIAL AGRICULTURAL CHEMISTS**. Compiled by Committee on Editing Methods of Analysis. Washington: Association of Official Agricultural Chemists, 1931. 593 pp. Price, \$5.00.

**DIABETES: ITS CONTROL BY THE INDIVIDUAL AND THE STATE**. By Elliott P. Joslin. Cambridge: Harvard University Press, 1931. 70 pp. Price, \$1.00.

**PROCEEDINGS OF THE NATIONAL CONFERENCE OF SOCIAL WORK**. Chicago: University of Chicago Press, 1931. 702 pp. Price, \$3.00.

## A SELECTED PUBLIC HEALTH BIBLIOGRAPHY WITH ANNOTATIONS

**New York's Dipped Milk**—The findings of a commission of distinguished members answered certain questions of the health commissioner as follows: Loose milk is a potential health hazard which can be removed only by the prohibition of its sale (except under certain restrictions); but owing to economic conditions, it is recommended that the prohibition become effective in 1933. The full report will be published shortly and will be available.

ANON. Banning of Dipped Milk Recommended. *Weekly Bull. (N. Y. C. Dept. of Health)*, 20, 46: 341 (Nov. 21), 1931.

**Prenatal Hygiene Principles**—This British lecture on the remedies for the causes of maternal mortality indicates that there is little difference of opinion on the subject here and abroad. The exception is the British tendency for frank discussion of the importance of eugenics, birth control, and sterilization, subjects usually taboo in this enlightened land.

BROWNE, T. J. The Health of the Woman Citizen as Potential and Actual Mother. *J. State Med.* 39, 12: 688 (Dec.), 1931.

**Milk-Borne Infections**—After listing at length all the infections that may be transmitted through milk, the author of this British contribution agrees with his "discussers" that pasteurization is likely to prove merely a veil to blind the public to the necessity for the elimination of tubercle infection from the milk supply.

BURROW, H. Bacterial Contamination of Milk and Its Significance. *J. Roy. San. Inst.* 52, 6: 234 (Dec.), 1931.

**Preventing Heat Cramps**—Loss of salt in sweat is the cause of heat cramps, which may be relieved by the prophylactic

administration of sodium chloride tablets.

GLOVER, D. M. Heat Cramps in Industry: Their Treatment and Prevention by Means of Sodium Chloride. *J. Indust. Hyg.* 13, 10: 347 (Dec.), 1931.

**Infra-Red Radiation**—"Many people feel stuffy and uncomfortable in a closed room warmed by a plenum system, or by dark or dull red sources of heat," says the author, introducing some observation which he concludes will alter the theory and practice of ventilation and heating.

HILL, L. The Influence of Infra-Red Radiation in Relation to Ventilation and Heating. *J. State Med.* 39, 12: 684 (Dec.), 1931.

**Typhoid Fever Via Milk**—"Eighty cases of typhoid fever occurring in Salisbury, Maryland, in July, 1930, were traceable to one milk supply. On the farm producing this milk a typhoid carrier was found. He had probably assisted in handling the milk on July 4."

HURDLE, S. H. A Milk-Borne Epidemic of Typhoid Fever in Salisbury, Maryland. *J. Prev. Med.* 5, 6: 465 (Nov.), 1931.

**Thyroid Prophylaxis in Two Cities**—Here is an interesting comparison. In Detroit, the state and city health departments, the school board and medical profession united upon a practical program to provide iodized table salt throughout the city (at no increased cost to the consumer). As a result the incidence of goiter was greatly reduced. In Cleveland, thanks to the exploitation of the possible danger that iodine might produce hyperthyroidism, the authorities abandoned a similar goiter prevention project and the medical profession was unable to agree on a plan. As a result, Cleveland continues to enjoy its incidence of thyroid enlargement.

KIMBALL, O. P. The Prevention of Goiter in Detroit and Cleveland. J. A. M. A. 97, 27: 1877 (Dec. 19), 1931.

**Adult Poliomyelitis**—In the epidemic studied, both sequelae and mortality rate were worse in adult cases than among children and serum therapy seemed far less encouraging.

LIMPER, M. A. *et al.* Poliomyelitis in Adults: Report of 60 Cases. J. Prev. Med. 5, 6: 475 (Nov.), 1931.

**Bacterial Dissociation**—Another contribution to our knowledge of bacterial dissociation. In this report the variations in the cultural characteristics of a coli-like organism are recorded. This paper may be read with profit by sanitarians who studied a "cut and dried" bacteriology.

NUNGESTER, W. J. and ANDERSON, S. A. Variation of a *Bacillus Coli-Like* Organism. J. Infect. Dis. 49, 6: 456 (Dec.), 1931.

**Septic Sore Throat Studies**—A general statement of the incidence, manifestations, and diagnosis of septic sore throat with a discussion of the bacteriology of *Streptococcus epidemicus*.

PILOT, I. and DAVIS, D. J. Sporadic Septic Sore Throat. J. A. M. A. 97, 23: 1691 (Dec. 5), 1931.

**Breast Feeding vs. the Bottle**—Don't miss this collection of opinions. Dr. R. M. Smith says, "Breast feeding is particularly important during first six weeks of life; it is desirable during first three months. . . ." Dr. W. P. Lucas says, "Except for conferring certain immunity, all other requirements are more easily met by a formula. . . ." Dr. C.

G. Grulee, "My own feeling is that the pendulum is swinging back to breast feeding. . . ." Dr. W. McK. Marriott, like his predecessors, admits the desirability of breast feeding; he does not argue against it, but is against "unintelligent fetishism." There is more to come in the next issue.

SMITH, R. M. *et al.* Are Infant Feeding Methods Changing? Pub. Health Nurs. 23, 12: 581 (Dec.), 1931.

**Mass Protection Against Measles**—A British discussion of the advisability of exposing infants to measles to be followed by a partially protective dose of convalescent serum. The limitations of alternate schemes are considered.

STOCKS, P. Some Observations on the Control of Measles Epidemics. Brit. M. J. 3699: 977 (Nov. 28), 1931.

**Mass Prophylaxis Against Colds**—Autogenous vaccine made from throat cultures was offered to a group of employees. Among the inoculated, 35 per cent lost time, whereas over 50 per cent of the untreated were absent because of catarrhal conditions.

STOWELL, T. E. A. Some Factors in the Reduction of Absenteeism Due to Catarrhal Conditions. Brit. M. J. 3699: 985 (Nov. 28), 1931.

**Cancer Research**—This report of very limited success in the treatment of epitheliomas with pituitrin plus theelin will probably become public property, for it has been mentioned in a news magazine. Health officials should be cognizant of this paper.

SUSMAN, W. The Rôle of the Pituitary in the Etiology of Cancer. Brit. M. J. 3695: 794 (Oct. 31), 1931.

## NEWS FROM THE FIELD

### FRENCH EQUATORIAL AFRICA

**I**NFANT health centers have been established in French Equatorial Africa, in some districts of which one-half of the infants die in their first year. This high mortality rate is attributed mainly to the ignorance of the native mothers. At the infant health centers, the public health physicians in the service of the French Government examine the children and teach the mothers the rules of hygiene. In order to assure attendance, gifts are distributed to the mothers, such as clothing for the children, soap, salt, and other things; larger gifts are given to mothers whose children show evidence of good care. Contests with money prizes are also being held. As a result of this work, in 2 years the infant mortality has decreased 8 times in one place and 20 times in another.

In some places groups of European women have organized prenatal and child health work among the natives. They maintain health centers, employ physicians and native visiting nurses, and distribute aid to mothers of little children.

In some of the important centers of population, training courses are provided for native midwives who are later stationed in the villages. Maternity hospitals have also been built in a number of places with funds obtained partly from the Government and partly from private sources.

Similar work is being done in French West Africa where, in addition, health centers have been established for school children and steps have been taken for the improvement of the vital statistics pertaining to the native children.—Of-

fice International d'Hygiène Publique, *Bulletin Mensuel*, Paris, Oct., 1931, pp. 1829, 1834.

### PUBLIC HEALTH CODE OF CHILE

**T**HE recently published public health code of Chile has a section on the health of mothers and children. Among other things, it orders the National Department of Health to establish health centers for expectant mothers and children. The department will also supervise the work of all institutions or agencies concerned with the welfare of the mother and child, whether public or private, whenever they are subsidized by the State. The health work of the State is to apply to children from birth until the end of the school attendance period and to mothers from the beginning of pregnancy until the end of the 6th month after the child's birth. Besides health work, the State is also to give other forms of aid to mothers and children, the details of which are to be prescribed in later regulations. Dependent mothers and children in the above mentioned periods of their lives are to be given free maintenance in public institutions.

No mother is allowed to nurse another child before her own is 5 months old, unless a physician certifies that she is able to nurse two children at the same time. This fact must be reported to the public health authorities, who are required to investigate the case.

The preventive health work for school children will be in charge of the National Department of Health; private schools must maintain medical service for their pupils in accordance with the rules of the department.

Dental clinics for mothers and children are to be established in the larger cities.—*Diario Oficial de la República de Chile*, July 6, 1931.

#### MATERNAL AND CHILD HEALTH CENTERS IN FRANCE

A STRONG movement is now going on in France for an increase in the number of maternal and child health centers as a means of checking infant mortality. Several of the departments of France have established such centers, but it is considered important to extend the system to the entire country, both urban and rural districts. For this purpose, the Minister of Public Health recently issued a circular to the prefects urging them to establish such centers throughout their respective departments and prescribing in detail their organization and functions. Several bills for that purpose are pending in the French Parliament, but the Minister considers this matter too urgent to wait until the bills are passed.—*La Revue Philanthropique*, Paris, Oct. 15, 1931, p. 797.

#### ADDITION TO NEW YORK ACADEMY OF MEDICINE PLANNED

ON January 10, at the annual meeting, announcement was made by Dr. Linsly R. Williams, director of the academy; that construction of a \$400,000 addition to the New York Academy of Medicine would begin in the near future.

Prior to the meeting a testimonial dinner attended by more than 200 fellows of the Academy was given in honor of Dr. Williams. In his address the director reviewed the activities of the academy during the last 8 years and outlined some of its plans for the future.

#### RESOLVED!

ON October 29, 1931, about 3 years after the organization of the Suffolk County Department of Health, the following resolution was unanimously adopted by the Suffolk County Medical

Society (N. Y.) at the largest annual meeting in its history:

RESOLVED, that the Suffolk County Medical Society hereby reaffirms its opinion first expressed in 1926 that public health administration can only be efficiently done by county organization (to replace township part-time organization); that after 3 years of experience the local profession more strongly than ever believes that the efficiency of public health practice is greatly improved by county organization; and that the physicians of the county have found that a county health department is an asset in their professional work and an asset to their economic welfare.

#### TEXAS WATER WORKS SHORT SCHOOL

THE Fourteenth Texas Water Works Short School was held at Mineral Wells, Tex., January 18-21. The program covered water supply, and sewage practices in general.

#### PERSONALS

DR. HAVEN EMERSON, F. A. P. H. A., was recently appointed by the President of the Merchant's Association of New York to succeed the late Professor Olin H. Landreth as Chairman of the Association's Committee on Sanitation, Public Health and Water Supply.

DR. JOHN W. MORR, of Albion, Ind., has been appointed Health Officer of Noble County, Ind., to succeed the late Dr. John H. Ravenscroft.

DR. THOMAS E. CARNEAL, of Winamac, Ind., has been appointed to fill the unexpired term of Dr. George W. Washburn, of Star City, Ind., who has resigned as Health Officer of Pulaski County, Ind.

DR. ALVIN H. ROCKWELL, member A. P. H. A., for 23 years Health Officer and Director of Health and Welfare of Kalamazoo, Mich., has resigned as of January 1.

DR. ALFRED F. HESS, of New York, member A. P. H. A., was recently elected to honorary membership in the German Pediatric Society.

DR. I. F. THOMPSON, F. A. P. H. A., of Syracuse, N. Y., has been appointed to succeed Dr. W. W. Bauer as the Health Officer of Racine, Wis.

DR. T. H. JOHNSTON, member A. P. H. A., of Athens, Ga., has resigned as secretary-treasurer of the Georgia State Public Health Association and Victor H. Bassett, M.D., has again been appointed to serve as secretary.

DR. C. W. DECKER has been appointed to succeed Dr. George Parrish as City Health Officer of Los Angeles, Calif.

April 19-23, 37th Annual Convention of the American Physical Education Association, Philadelphia, Pa.

May 10-15, Annual Congress of The Royal Institute of Public Health, Belfast, Ireland.

June 2-4, Third Annual Meeting, Western Branch, American Public Health Association, Denver, Colo.

June 6-9, National Tuberculosis Association, Colorado Springs, Colo.

### CONFERENCES

April 4-8, American College of Physicians, San Francisco, Calif.

April 11-15, American Nurses Association, San Antonio, Tex.

April 11-15, National Organization of Public Health Nursing, San Antonio, Tex.

April 11-15, National League of Nursing Education, San Antonio, Tex.

### MEDICAL BIOLOGY COURSE

Four year course leading to  
B.S. degree

Well equipped laboratories of the College, the Michigan State Department of Health and large city hospitals are available. Prepares for laboratory positions in chemistry, serology, bacteriology and pathology.

Catalog sent on request. Address Professor of Bacteriology and Hygiene, Michigan State College, East Lansing, Michigan.

### Course in Veterinary Medicine

Full four year college course leading to degree D.V.M. For information, address Dean of Veterinary Medicine, Michigan State College, East Lansing, Michigan.

## *Application for Membership*

I wish to apply for membership in the American Public Health Association.

Name.....  
Print name in full and give degree

Street and City..... State.....  
For correspondence and the Journal

Present public health occupation.....

**MEMBERS:** Persons professionally engaged in public health work from the United States, Canada, Mexico, and Cuba are eligible for election as Active Members. Persons interested in public health, from any country, are eligible for election as Associate Members.

**DUES:** Dues of Members of either class are \$5.00 per year, which includes an annual subscription to the American Journal of Public Health.

### Study in the Epidemiology of Diphtheria in Relation to the Active Immunization of Certain Age Groups<sup>\*†</sup>

EDWARD S. GODFREY, JR., M. D., F. A. P. H. A.

*Director, County Health Administration, State Department of Health,  
Albany, N. Y.*

IT has long been known that it is not necessary to destroy every Anopheline in a region to rid it of malaria; that the vaccination of much less than 100 per cent of a population is quite effective in preventing the spread of smallpox; that epidemics of measles cease long before the susceptibles are exhausted. But since it is commonly believed that diphtheria is usually spread by healthy carriers, grave doubt exists whether anything less than the immunization of the entire child population will suffice to reduce this disease to negligible proportions. However, several experiences in New York State during the past 9 years have seemed to indicate that if certain minor fractions of the population be immunized an epidemic of diphtheria will not occur or if present, will promptly subside after these fractions have been immunized. The determination of this question therefore is of great practical importance.

It can be taken as reasonably well proved that a considerable majority (65-95 per cent) of those given 3 injections of either toxoid or toxin-antitoxin thereby become immune to the disease. If this be all that happens then diphtheria will only be reduced among those treated and only to the extent that those treated actually become immune. On this assumption if half the children age 0-14 years are given 3 doses

<sup>\*</sup> Read before the Health Officers Section of the American Public Health Association at the Sixtieth Annual Meeting at Montreal, Canada, September 14, 1931.

<sup>†</sup> This is a part of a study to determine the effectiveness of procedures for the reduction of diphtheria, assisted by a grant from the Commonwealth Fund and under the auspices of the American Public Health Association through its Committee on Administrative Practice.

TABLE I

DIPHTHERIA DEATH RATES PER 100,000 POPULATION, AND PER CENT OF POPULATION IMMUNIZED \*  
BY AGE: NEW YORK STATE, EXCLUSIVE OF NEW YORK CITY AND ROCHESTER, 1920-1930

Year	Deaths per 100,000 population at age:				Per cent of population immunized at age:			
	All ages	Under 5 years	5-9 years	10-14 years	All ages	Under 5 years	5-9 years	10-14 years

1930	2.6	16.5	7.7	1.7	15.0	25.3	60.6	60.1

\* As of Dec. 31 of year stated.

of antigen and three-fourths of them become Schick negative only three-eighths of this age group would be protected. As three-fourths of the cases occur during this age period the diphtheria case rate should be reduced only by  $9/32$ , or approximately 28 per cent. On the same assumption, if only half as many children under 5 years be immunized

TABLE II

DIPHTHERIA DEATH RATES PER 100,000 POPULATION, AND PER CENT OF POPULATION IMMUNIZED \*  
UNDER 15 YEARS OF AGE: PLACES OVER 10,000 AND UNDER 10,000 POPULATION IN NEW  
YORK STATE, EXCLUSIVE OF NEW YORK CITY AND ROCHESTER, 1920-1930

Year	Deaths per 100,000 population in places:		Per cent of population immunized under 15 years of age in places:	
	Over 10,000	Under 10,000	Over 10,000	Under 10,000
1920	25.8	8.6

1927	5.8	3.7	17.1	11.0
1928	5.3	2.7	31.7	24.2
1929	4.7	2.5	41.1	30.1
1930	3.3	1.9	50.5	36.2
			58.9	40.7

\* As of Dec. 31 of year stated.

as children 5-9, the effect should be to reduce the incidence in the latter group twice as much as in the former.

As a matter of fact neither of these things seems to happen. Although in New York State more than twice as many children age 5-9 have been given toxin-antitoxin than age 0-4 the specific age death rates have declined with remarkable parallelism (Table I). Furthermore, this parallelism is equally striking in the rates for places over and places under 10,000 population despite a preponderance of immunizations in the former (Table II). These observations may be interpreted either as indicating that the recent decline in diphtheria is independent of active immunization, or at most only assisted by it—or that the protection of a certain part of the community affords a general protection and that a protected urban center serves to reduce the incidence in adjacent territory.

Efforts to prove a causal relationship between active immunization and declining annual diphtheria death rates by merely measuring deviations from a trend are quite unconvincing to one acquainted with

FIGURE I  
CASE AND DEATH RATES PER 100,000 POPULATION: AUBURN, 1913-1930

FIGURE II

CASE AND DEATH RATES PER 100,000 POPULATION: AMSTERDAM, 1913-1930

the behavior of these rates when unaffected by factitious influences. On the basis of their annual diphtheria death rates it is quite impossible to determine whether Auburn (Figure I), or Amsterdam (Figure II) was the scene of the first community-wide toxin-antitoxin drive, yet several thousand children were immunized in the former city and only 300 in the latter. Furthermore, if the declines in the death rates in New York City and Philadelphia can be attributed to large but indefinite numbers of immunizations, how do we account for the failure to produce a like effect in Newark, Detroit, and Buffalo?

It is believed that the answer may lie in two generalizations induced from certain observations made during the past 9 years which may be stated as follows:

1. The attainment of a high degree of herd immunity among children 5-9 and 10-14, as evidenced by the injection of 3 doses of toxin-antitoxin in 50 per cent or more of the members of these groups, produces no definite effect on the diphtheria

incidence in that community. Diphtheria if prevalent continues prevalent for a considerable period and declines gradually as it does when active immunization is not used. If not prevalent an outbreak of considerable proportions may arise.

2. However, when the immunization of approximately 30 per cent or more of the children under 5 years is superimposed, there is an immediate definite decline in the current prevalence, and if the community be free from the disease or if its prevalence be low an outbreak is very unlikely to occur.

*In other words, there is a critical point in the under 5 age group which must be attained and sustained in order to affect the diphtheria rate favorably.*

Whether the immunization of 30 per cent or more of the under 5 age group would be effective without any immunizations among older children cannot be determined. There is no evidence on this point and it seems unlikely that any community will so strictly limit immunizations to children under 5 years as to provide that evidence.

The observations which have led to the above hypothesis and a brief attempt to rationalize it with our knowledge of the epidemiology of diphtheria follow:

Auburn, N. Y., as everyone knows, was the scene of the first attempt to eradicate diphtheria on a community-wide basis through the use of toxin-antitoxin. As will be seen in Figure III (see note), the disease had been prevalent for 3 years when in February, 1922, the campaign was started by Dr. Sears. It will be noted that during this early period (1) nearly 50 per cent of the children age 5-9 and 10-14 were either found Schick negative or given 3 doses of toxin-antitoxin; (2) the 0-4 age was neglected; (3) there was a recrudescence of the outbreak in the fall and winter of 1922-1923; (4) in this city of 30,000 although never attaining the proportions of an outbreak diphtheria continued present almost every month for over 3 years and was not effectively curbed until after July, 1928; (5) in May, 1928, the cumulative percentage of children under 5 years first reached 30 per cent of those in this group; (6) the proportion of children 5-9 and 10-14 increased to 60 per cent and 70 per cent respectively without marked effect on the residual diphtheria.

The recrudescence in the fall of 1922 was attributed at the time to the belief that it required 6-9 months to produce immunity with the toxin-antitoxin then in use. It is now believed that it was due to the

NOTE: The declination in the lines showing the percentages of children immunized is based on the assumption that one-twelfth of the children age 4 will graduate each month into the age group 5-9. Hence, if the immunizations in the group over a period of time are fewer than the graduations from it, the percentage of immunized children in that group will fall accordingly. Similarly the children in the 5-9 age group are assumed to graduate at a uniform rate into the group 10 years and over. The losses in this group, however, may be more or less counterbalanced by graduations from the age group below it.

FIGURE III

fact that children in the under 5 age group were not reached and that the subsequent decline in diphtheria could in large part be attributed to the usual recession from a period of high prevalence.

Nearly 5 years later, in the fall of 1926, Newburgh, N. Y., population 30,000, carried out a campaign of immunization during an epidemic that had lasted about 18 months (Figure IV). Normally we should have expected it to last through the succeeding winter probably attaining its maximum for the epidemic year in December or January. Observe that approximately 35 per cent of the 0-4 and 65 per cent of the 5-9 age groups were treated during a period of about 6 weeks. Note also the almost complete disappearance of diphtheria immediately following and its continued absence.

In the spring of 1927 a similar campaign was carried out in Utica, N. Y., population 100,000 (Figure V). The administration of toxin-antitoxin during 1926 to 7,000 school children, comprising 40 per cent of the 5-9 age group, 30 per cent of the 10-14 group and only 2 per cent or 3 per cent of the under 5 group, had had no effect on the mass incidence the following winter. The 1927 campaign raised the 5-9 group to 60 per cent, the under 5 group to nearly 40 per cent and the

FIGURE IV

FIGURE V

FIGURE VI

DIPHTHERIA CASES AND PER CENT OF POPULATION IMMUNIZED, EACH MONTH BY AGE

decline was immediate and rapid. The percentages have been quite well maintained and the diphtheria incidence has remained low. It is possible that the decline in Utica may have been simply a recession from an epidemic. An examination, however, of the monthly incidences of diphtheria unaffected by toxin-antitoxin in 22 cities of more than 25,000 population covering a period of 23 years fails to disclose an instance of as rapid a decline with a subsequent incidence so low.

The next example occurred in Albany, N. Y. (Figure VI), population 120,000. Approximately 5,000 children had been given toxin-antitoxin during the 2-3 years preceding the beginning of a quite explosive outbreak late in 1927. The northern section of the city was the principal focus and an immediate campaign was initiated designed primarily to reach children under 5 years. The immunizations were concentrated at first on the affected district but extended later to all parts of the city. The outbreak promptly subsided though a little less than 30 per cent of the under 5 age group were given toxin-antitoxin. It is highly probable, however, that a much higher percentage was attained in the affected district. Due to graduations, the percentage of children under 5 diminished to 20 per cent during 1929 where it remained until 1930 when another drive placed the figure above 30 per cent. The reduced endemic incidence since then is apparent.

This outbreak is among those deserving further study. No evidence that it was milk-borne was adduced and the age distribution is against this hypothesis.<sup>1</sup> On the other hand, the question arises as to what percentage of children in the different age groups living in the affected area were given toxin-antitoxin. Unquestionably it was much higher there than in the city at large. The continued presence of rather numerous cases until the latter part of 1930 shows that the city as a whole was not well protected. The geographical distribution of those later cases is another point yet to be investigated. Have they occurred in those parts of the city that have been relatively neglected or has the area of intensive work had its full share?

Niagara Falls (Figure VII), population 75,000, had given toxin-antitoxin to over 6,000 children and reached approximately 60 per cent of the children 5-9 by the end of 1927. Diphtheria had been prevalent the preceding winter and spring, continued at a lower rate through the summer and increased sharply in January, 1928. A well conducted drive by the city health officer resulted in raising the 5-9 age group to over 70 per cent and the under 5 age group from less than 10 per cent to over 40 per cent in the course of a few weeks. Note the marked drop immediately following and the comparative absence of cases until this past winter. This increase seems to be an exception to the rule and will be discussed further.

FIGURE VII

DIPHTHERIA CASES AND PER CENT OF POPULATION IMMUNIZED EACH MONTH, BY AGE

FIGURE VIII

DIPHTHERIA CASES AND PER CENT OF POPULATION IMMUNIZED EACH MONTH, BY AGE

Figures VIII and IX are to illustrate the failure to produce a marked effect on the community incidence of diphtheria through giving toxin-antitoxin to 50 per cent or more of children age 5-9.

FIGURE IX

DIPHTHERIA CASES AND PER CENT OF POPULATION IMMUNIZED, EACH MONTH BY AGE

If one be satisfied with mere numbers, Buffalo's effort should be most gratifying. Three doses of toxin-antitoxin were given to 28,800 children in that city in 1927, to 17,700 in 1928, 31,000 in 1929, 16,000 in 1930. During the 6 years ending December, 1930, it had been given to 95,935 individuals, an impressive number, though not an extraordinary percentage of the population. The age distribution of those given toxin-antitoxin and the failure of this work to produce any marked effect on the diphtheria incidence are shown in Figure VIII. More than 50 per cent of the age group 5-9 has been protected since the middle of 1929, and the attainment of even 70 per cent in this group plus over 20 per cent in the under 5 year group, has not sufficed to reduce materially the diphtheria incidence.

In Yonkers, population 130,000 (Figure IX), the period of high prevalence began in 1923, attained its maximum in 1927, and declined slowly through 1928 and the first half of 1929 when it became stabilized. Giving toxin-antitoxin to 50 per cent of the 5-9 age group and even 70 per cent of this group plus 25 per cent of the under 5 group produced no striking effect on the diphtheria incidence; except that stabilization is at a much lower figure than any ever previously attained by this city, the decline might well be due to "natural causes."

Failure to prevent a sharp increase in cases though 50 per cent of the 5-9 age group have been treated is illustrated by the following examples:

Poughkeepsie (Figure X), population 40,000, experienced an increase of cases beginning in the spring of 1927 and culminating the following fall and winter although about 50 per cent of the 5-9 age group had been given toxin-antitoxin. Following a drive in the late spring of 1928 during which slightly more than 30 per cent of the under 5 year group were given toxin-antitoxin there were no cases during the last 5 months of the year. The occurrence of 15 cases the following year despite the fact that the 5-9 age group was held at from 60 per cent to 70 per cent and the under 5 group never got much below 30 per cent suggests that these percentages afford little or no margin of safety.

Cohoes (Figure XI), population 23,000, after a 3-year period of high prevalence, had a well marked increase in the late fall of 1929 despite a 50 per cent protection of the 5-9 age group. The gradual rather than sudden subsidence may be noted. The occurrence of but 2 cases during the 11 months ending June 1, despite failure to immunize 30 per cent of the under 5 age group, is not unusual in places of this size.

*Exceptions*—A search of our records for the past 5 years has dis-

FIGURE X

DIPHTHERIA CASES AND PER CENT OF POPULATION IMMUNIZED EACH MONTH, BY AGE

closed 2 instances of sharp increases in the diphtheria incidence in places having 30 per cent or more of the under 5 age group protected. One of these, that in Niagara Falls (Figure VII), has already been alluded to, the other was in the village of Port Chester, population 20,000, in the late spring and early summer of 1929 (Figure XII). They are both being studied further, neither study being as yet complete. However, as together they indicate something of the method of approach, the material is presented for information and discussion.

In Niagara Falls the geographical relations of the cases to the births occurring during 1930 have been studied; the births being taken as an index of the distribution of the child population. The area of prevalence in the recent outbreak has also been compared with the preceding one in 1927-1928. The two have been found to overlap only in the central southern part of the city. In relation to the birth map the earlier outbreak was found to conform more closely to the child population distribution than the recent one although one densely populated area was but little affected in either outbreak. It is proposed next to study the geographical distribution of the children who have had toxin-antitoxin both in relation to the births and to the cases of diphtheria. Whether an approximate numerical relationship can be obtained is of course to be determined.

FIGURE XI

In Port Chester the geographical relationship of the cases to the children given toxin-antitoxin has been studied through a spot map showing the location of cases and immunized children. This map was kindly prepared for me by Dr. W. A. Holla of the Westchester County Health Department from the village records. The next step will be to relate cases and immunizations to the distribution of the child population.

The outbreak itself deserves a brief description since it represents much more complete case reporting than is found in the ordinary run of outbreaks. Furthermore it is not an exaggeration due to the inclusion of carriers. Every case included, I am informed, either had definite clinical symptoms of diphtheria when seen by a physician or gave a clear history of an attack that could not well be interpreted otherwise. The completeness of reporting was due to the activity of the village nurse who ferreted out the cases both among the known contacts and the children of the neighborhood. It is worthy of mention that all of these cases could be attributed to contact with a prior case, missed or recognized, but in any event an individual with a pathological condition that could have been due to the diphtheria bacillus.

We were informed upon inquiry that the section of the village in

FIGURE XII

DIPHTHERIA CASES AND PER CENT OF POPULATION IMMUNIZED EACH MONTH, BY AGE

which this outbreak occurred had not responded as well as other sections in having the children given toxin-antitoxin. This contention is not borne out by Dr. Holla's map. Obviously, however, the density of the child population in this area is a factor and no distinction is made on the map of immunized children over and under 5 years old. These are points for further investigation.

Of exceptions outside New York State the only one I have been able to discover is Detroit. Vaughan and Buck<sup>2</sup> have recently described the work in that city and I have since received further data from Dr. Gudakunst of the Detroit Health Department. The figures published in Vaughan and Buck's article indicate that only 21 per cent of the under 5 age group had been "immunized." It is important to note that the age group for which they give a "protection percentage" of 29.12 includes children up to 6 years. In New York we have adhered to the standard age groupings both because of convenience in comparing with morbidity, mortality, and population, and because age, rather than school attendance, is the important factor in determining mortality and preventing morbidity.

On the 21 per cent basis Detroit does not constitute an exception. However, during the first quarter of 1931 a canvass of some 91,000 children under 5 indicates that 58.3 per cent had been treated, a large

portion of them presumably during recent months. The effect on the morbidity rate has not been particularly striking. The unique system for diphtheria prevention being followed in Detroit, and the fact that the figure mentioned represents the results of a canvass requires further investigation to determine to what degree their records compare with ours. It would appear from comparing the reports on toxin-antitoxin in cities in New York State made to the White House Conference with those we have compiled in the State Health Department from the reports of local health officers that the latter tend to minimize and the canvass or census tends to exaggerate the actual degree of protection. Out of 9 cities in only 3 was the agreement as close as 5 per cent, one of these 1 per cent lower, the other 2 higher. In all the others the conference rating was from 6 per cent to 17 per cent higher. As the conference used the abominable under 6 years age grouping and as many more children have been given toxin-antitoxin at age 5 than at any lower age, it is probable that the agreement is closer than appears.

As it is hoped to accumulate comparable data from a large number of places during the next few years, a high degree of uniformity in the method of collecting and tabulating immunization statistics is a necessity. It seems desirable, therefore, to describe in some detail the methods we have worked out in New York State during the past 7 years, not with the idea that they are necessarily the best, but because we probably have more data, tabulated uniformly, to serve as a basis of comparison than can be found anywhere else. Any community that has good primary records of toxin-antitoxin administration can with more or less trouble follow this system and determine its approximate immunization status as of any given date.

The primary data come to the local health officer from four different sources: The practising physicians, school clinics, regular children's clinics and special toxin-antitoxin clinics. Forms have been devised to facilitate record making for each of these but the form most widely used is known as Form 50; the "Request Card," which is adaptable to all purposes (Figure XIII). It is intended primarily for use by a canvasser who inserts names and ages on the front, secures the parents' signatures and notes on the back the time and place of the clinic the children are to attend. If they purpose going to a private physician, his name is entered in lieu of the clinic. The card is indexed by family name and taken to the clinic where the entries are made at the time the injections are given. On completion of the third injection it is transferred to a file for current completed cases where it remains until tabulated, after which it goes to the permanent file for completed cases. Other details are not germane to this discussion and are, therefore, omitted.

The data come to the State Department of Health as simple tables on what is familiarly known as "Form One Forty" (Figure XIV). Only the figures in the first column are used and they are entered on work sheets as received and are tabulated monthly for purposes that need not concern us here. Annually or oftener as occasion requires they are assembled into a table (Figure XV) for each place over 10,000 population and for each county exclusive of such places. This table shows the corresponding figures for the previous years in columns to the left. By drawing a line under the figure for age 4 of the last or current year, under age 3 for the next preceding year, under age 2 for the year before that, and so on, and then by connecting these lines by diagonals, the figures showing the number whose present age is under 5 become apparent and are easily added together. A similar line starting under age 9 will indicate the figure for the 5-9 group. By consulting the "Form One Forty" reports and noting the months covered by them refinement is possible. It is used in special cases, as for example, in Figures II to XII illustrating the experiences of cities in New York State. It is unnecessary to go into details for after all we are dealing with approximations and refinement is rarely justified.

It is now proper to rationalize the hypothesis, to offer an explanation of how it is possible by immunizing a fraction of the population to decrease materially the incidence of such a disease as diphtheria. It seems to be generally accepted that all that active immunization does is to prevent the development of an *attack* of clinical diphtheria; that

REMARKS (Note unusual reactions or any other items of interest)

it does not prevent the individual from becoming a carrier. It is by no means certain that this is so, the little evidence we have on the point being equivocal. The subject is one for further study.

A reduction in the carrier rate, however, even if it occurs, is probably a relatively minor factor. It may operate to keep the rate below the threshold of epidemicity as suggested by Glover<sup>1</sup> for meningitis but it seems to me more probable that the carrier plays a relatively beneficent rôle as the cheapest source of naturally acquired immunity.

As Doull and Lara<sup>6</sup> have shown, the incidence of secondary cases in families with reported clinical cases of diphtheria is at least 10 times and is probably more than 15 times as high as in families with carriers. As compared with families in which carriers were not known to exist, they concluded that families of carriers incurred a small but distinctly greater risk.

The secondary carrier rate in these carrier families and the Schick reactions of the contacts before, after and during the period of exposure are not given. We know from Frost<sup>7</sup> that about 47 carriers develop for every case that develops from the casual exposures of school children while only 6 carriers develop for every case that develops from exposure to known cases. *In other words, carriers tend to develop carriers and presumably immunity, while cases have a much greater tendency to develop new cases.* These observations pointing to the innocuousness of the individual carrier as compared with the individual case do not, of course, rule out the carrier as the principal source of recognized diphtheria. The Baltimore studies indicate that only about 23 per cent of the recognized cases can be traced to a previous case, the inference being that the remaining 77 per cent are due to contact with carriers. Though a large city is not the best place in which

to attempt this sort of a determination yet, as far as *sporadic* and *endemic* cases are concerned it seems logical that the vast majority are due to carriers.

It does not follow, however, that the cases occurring during a period of high prevalence are mainly due to carriers and I can see no reason for the apparent results from immunizing a minor fraction of the child population if this be true. It would seem that the result must come from the prevention of cases. As the known cases cannot be held responsible for the spread of the disease, it follows that the great majority of these cases are not recognized as diphtheria. They are probably then atypical, the so-called larval cases, the cases that are not seen by a physician, that are missed unless an assiduous search is made for them. As the immunization of a small fraction of the under 5 age group seems to produce a more marked effect than a larger fraction of older children, it seems likely these cases exist in greatest numbers in this youngest group.

One of the rarest types of diphtheria reported to health departments is nasal diphtheria. I refer particularly to the type in which the infection is limited to the anterior nares. This condition is usually extremely mild and yet is said to be very common among infants and younger children. If in taking routine cultures they are found to harbor diphtheria bacilli they probably are classed as "carriers" though there is little doubt that the discharge is due to an underlying pathology due to the diphtheria bacillus. I have some evidence that these cases do not occur in children with antitoxin immunity. These cases are especially dangerous because—(1) they rarely suffer from toxemia and hence move about freely, and (2) the infectious discharge is on the surface where it is readily available. It is perhaps the prevention of a considerable number of such cases that stops an epidemic.

#### SUMMARY

1. The injection of 50–70 per cent of children over 5 years old with 3 doses of toxin-antitoxin has failed in numerous instances to produce any marked effect on the diphtheria incidence of a community.

2. The immunization of 30 per cent or more of children of the under 5 age group in addition to more than 50 per cent of children 5–9 has in several instances produced an immediate and striking decline in the diphtheria rate of the community as a whole.

3. The promptness of this seeming response suggests that a high degree of immunity is quickly acquired by a majority of those given 3 doses of toxin-antitoxin. It is a matter probably of a few weeks rather than several months. The point is worthy of further investigation.<sup>8</sup>

4. In only 2 instances known to the writer has a community that had attained 30 per cent immunization of its under 5 age group suffered even a moderate epidemic.

5. It is possible that immunization of the under 5 age group should not be uniformly distributed through the community, but should be largely concentrated in sections of highest prevalence if diphtheria is prevalent; if not, then in the congested areas.

6. This study is presented as a working hypothesis, worthy of trial as a means of quickly ridding a community of epidemic diphtheria. Much more data from more varied sources are necessary to establish its validity. To this end uniformity in the tabulation of immunization statistics is a necessity. The Committee on Administrative Practice and all health departments should adopt the standard age grouping in their tables, should classify immunizations by single years of age up to 10 years and should annually or oftener so tabulate their material as to show the present status.

7. It is suggested that the unrecognized case rather than the healthy carrier is responsible for the occult infections occurring during epidemics or periods of high prevalence. It seems not improbable that many mild nasal cases would be discovered if diligently sought. Such cases are the ones most likely to spread infection.

Finally it should be clearly understood that this presentment is in no sense a plea for any community to stop work when it has attained a 30 per cent immunity. That figure may be much too low. Active immunization, like antitoxin, was introduced on a wholesale scale during a period when diphtheria was receding from a period of high epidemicity. It is, therefore, the more difficult to measure its effect. The immunity conferred may not suffice for an organism of greater invasiveness, virulence, and pathogenicity.

In any event, the only reasonably sure protection for the individual is individual immunization. The one unvaccinated individual in the city may be the gas station man who serves an itinerant smallpox case. The one infected mosquito may bite a susceptible.

# Numbers of Bacteria in Frozen Food Stored at Several Temperatures\*

PROFESSOR SAMUEL C. PRESCOTT, F. A. P. H. A.

*Department of Biology and Public Health, Massachusetts Institute of Technology, Cambridge, Mass.*

PHILIP K. BATES, PH. D., AND MATTHEW E. HIGHLANDS

*Bacteriological Laboratory, Frigidaire Corporation, Dayton, O.*

THE introduction of new methods commonly known as quick freezing has given a decided impetus to preservation of food by storing in a chilled or frozen condition. The early development of the process was carried out for the preservation of fish but it has been modified for meats and more recently for vegetables and fruit. In addition to the introduction of quick frozen natural products, many varieties of berries and fruits have been packed in sugar and frozen. This product was developed to provide uncooked fruit for ice cream manufacturers and is extensively used in bakeries and for other manufacturing processes.

While much progress has been made in the experimental development of preservation by freezing, and recent merchandising experiments have shown that the products are well received by the public, there is every indication that still wider application will lead to new products and to tremendously larger sales in the fields already explored.

The general practice is to freeze the product at or near the point of production and then store it, as opposed to the former procedure of storing food in a warehouse and then freezing. In general, the newer products are carefully packaged and are ready to be sold by the retailer without any further preparation. Many have been sold in a frozen condition although some are thawed of necessity, facilities for maintenance in a frozen condition being lacking, and some are thawed to make them more acceptable to the customer. The temperatures for freezing and storage are, in general, considerably lower than those formerly employed.

The products are so new that no markedly different household

---

\* Read before the Food, Drugs and Nutrition Section of the American Public Health Association at the Sixtieth Annual Meeting at Montreal, Canada, September 13, 1931.

procedures for handling have come into use; they are being treated in approximately the same manner as though fresh. This has, in general, been satisfactory.

The exact character of the changes in food products during the stages of preparation, freezing, storage, and transportation, have not been well established. Criteria of fitness have not been widely published, but it is obvious that control of the manufacturing and merchandising of these products requires definite standards in the interests of public health. Before these can be set a large volume of information is needed concerning the natural changes which take place under carefully controlled conditions.

#### EXPERIMENTAL PROCEDURE

In an attempt to secure general and specific information on the matter, it was determined to obtain samples of commercially frozen food, wherever possible, and expose them to conditions that would simulate the expected retail storage conditions. By observation over a long period, it was believed that changes would be measurable, and that by correlation of these, some standards for satisfactory storage could be set up.

This paper is a preliminary report and includes data on 6 articles: haddock, lamb chops, spinach, strawberries, raspberries, and orange juice, selected as representing the classes of foods most often treated by this process. With the exception of the orange juice, all samples were quick frozen by the Birdseye process, and were received in the laboratory in a condition similar to that which would be expected if they were being removed from the storeroom for distribution to the retail dealer. Although some were freshly frozen, all had been kept at very low storage temperature, probably  $-29^{\circ}$  C. ( $-20.2^{\circ}$  F.). The samples of orange juice came from two plants that were freezing the juice commercially, and were shipped with dry ice refrigeration.

On receipt in the laboratory, samples were divided and stored in Frigidaire cabinets at temperatures of approximately  $-18^{\circ}$  C. ( $0.4^{\circ}$  F.);  $-12^{\circ}$  C. ( $10.4^{\circ}$  F.);  $-6.6^{\circ}$  C. ( $20^{\circ}$  F.).

Examinations were in general made at intervals of 1 week at the start, which were lengthened to 2 or 4 weeks as the test progressed. The bacterial examinations were made by cutting aseptically a piece of approximately 5 gm. This was weighed in a sterile mortar, ground with sterile sand, and the whole transferred to a dilution bottle. Dilutions and plating were carried out in the usual manner. Difco nutrient agar was used. The plates were incubated at  $25^{\circ}$  C., and in some cases duplicates at  $37^{\circ}$  C.

## DISCUSSION

The bacteriological examination was on successive samples rather than successive tests on the same sample. As they were all commercial or semi-commercial it would be expected that they might vary in the number of bacteria, and therefore the numbers recorded on the various examinations might be expected to fluctuate. In products that showed wide variations in numbers before freezing, such fluctuations would be particularly noticeable. The order of magnitude is therefore of more significance than the actual counts. A brief statement of the trend of bacterial numbers for each food will perhaps be most useful in presenting the facts.

*Lamb Chops*—The numbers of bacteria present in lamb chop fat (Table I) were not particularly high in any case. In general, a reduction at all storage temperatures is shown. At  $-6.6^{\circ}\text{C}$ . there is an indication of an increase through the 2d week followed by a decrease. At  $-12^{\circ}\text{C}$ . a similar condition occurred with a peak at the 4th week, though it is difficult to know whether this is a true peak or an erratic high count. At  $-18^{\circ}\text{C}$ . the counts are very irregular and it is not easy to draw any conclusion except that the temperatures may have held the numbers so nearly constant that they reflect the original bacterial content more truly than do the higher temperatures. No counts were made on the lean portion of the chops.

TABLE I

BACTERIA IN THE FAT OF QUICK FROZEN LAMB CHOPS AT 3 STORAGE TEMPERATURES

*Numbers of bacteria per gm.*

Storage Time	$-6.6^{\circ}\text{C}$ .	$-12^{\circ}\text{C}$ .	$-18^{\circ}\text{C}$ .
Start	107,000	107,000	107,000
1 week	359,000	41,200	169,000
2 "	472,000	222,000	89,200
4 "	101,000	346,000	145,000
6 "	38,300	44,400	67,700
8 "	69,100	61,200	26,400
10 "	14,000	46,300	46,100
12 "	3,950	56,500	191,000

*Strawberries*—The numbers of bacteria in the strawberries (Table II) were quite low for the most part. There were noticeable reductions at  $-6.6^{\circ}\text{C}$ . and  $-12^{\circ}\text{C}$ . There are indications that the reduction was more marked and quicker at the higher temperatures. There was little change at  $-18^{\circ}\text{C}$ . A possible cause of this apparent anomaly will be discussed later.

TABLE II  
BACTERIA IN QUICK FROZEN STRAWBERRIES AT 3 STORAGE TEMPERATURES  
*Numbers of bacteria per gm.*

Storage Time	-6.6° C.	-12° C.	-18° C.
Start	1,900	1,900	1,900
1 week	2,000	2,180	2,520
2 "	700	1,400	2,670
4 "	400	680	830
6 "	280	960	2,200
8 "	700	750	1,000
10 "	—	503	2,000
12 "	183	—	1,780

*Raspberries*—Table III indicates that most of the findings noted for strawberries hold for raspberries, except that in a few instances considerably higher counts were obtained.

TABLE III  
BACTERIA IN QUICK FROZEN RASPBERRIES AT 3 STORAGE TEMPERATURES  
*Numbers of bacteria per gm.*

Storage Time	-6.6° C.	-12° C.	-18° C.
Start	50,500	50,500	50,500
1 week	29,200	984	10,800
2 "	1,170	739	3,830
4 "	—	523	313
6 "	275	638	1,520
8 "	726	4,720	1,220
10 "	104	631	1,380
12 "	9,770	709	786

*Spinach*—The counts for spinach (Table IV) were in general somewhat higher than for strawberries and raspberries. The numbers at -6.6° C. include several counts that were noticeably higher than at either of the lower temperatures. Counts at -12° C. and -18° C. were fairly uniform and probably indicate there was very little change in numbers.

*Haddock*—The counts on frozen haddock (Table V) were in general more uniform. The incubation temperature was 37° C. as contrasted with 25° C. for all the other foods. Later work has shown that this temperature is not satisfactory and probably explains the low initial count, as the fish had been kept at extremely low temperatures with dry ice for a number of hours during shipment.

TABLE IV

Disregarding some irregular high counts the numbers in the  $-4^{\circ}$  C. samples were low. The numbers in the  $-6.6^{\circ}$  C. samples apparently show a continuous reduction. At  $-12^{\circ}$  C. the numbers were never high, and there were indications of a gradual reduction. The counts on the  $-18^{\circ}$  C. samples were too irregular and too scattered to warrant definite conclusions.

*Orange Juice*—The counts on frozen orange juice were somewhat irregular, due, it is believed, to irregular infection during processing and differences in sampling. There were definite indications that constantly higher counts were obtained from samples stored at lower temperatures.

In general, the results obtained did not indicate any continued increase in organisms at the temperatures studied. There were very definite indications that reductions occurred as storage time increased.

The noticeably higher numbers of organisms in some of the foods stored at lower temperatures are not easily explained, but may be due to the fact that the particular foods do not furnish satisfactory soils for the organisms, and the lower temperatures delay the germicidal effects.

CONCLUSIONS

From the limited number of experiments it is difficult to formulate conclusions, but there is every indication that frozen food, if carefully prepared and stored, can be merchandised with an adequately low microörganism content. Fluctuations were noted at all storage temperatures studied.

The small numbers of bacteria present and the temporary slight increases noted do not seem sufficient to explain the chemical and physical changes (limited changes in pH, titratable acidity, weep, color, etc.) detected. The general decreases in numbers of bacteria noted make it seem still more unlikely that microörganisms are the sole or even the principal cause of these changes, which probably are enzymatic.

In certain foods the decreases in numbers of bacteria occur more rapidly and to a greater degree at the higher storage temperatures, and this may be due to the lack of the protective action of extreme cold against the unfavorable environment provided the organisms by the foods.

# Bacteriological and Antigenic Analysis of *Shigella Paradysenteriae* Sonne Isolated from 9 Cases\*

HENRY WELCH, PH. D., AND FRIEND LEE MICKLE, F. A. P. H. A.

*Research Biologist and Director, Bureau of Laboratories, Connecticut State  
Department of Health, Hartford, Conn.*

THE importance of *Shigella paradysenteriae* Sonne† as the cause of acute and mild cases of diarrheal disease in this country has been emphasized by the investigations of Nelson<sup>1</sup> and MacKenzie and Batt.<sup>2</sup> As pointed out by Nelson, the association of late-lactose-fermenting organisms of the paradysentery group with diarrheal disease was first noticed by Duval and Schorer<sup>3</sup> in 1904. It was not until 1915 that Sonne<sup>4</sup> demonstrated as the main causative agent of dysentery in Copenhagen a late-lactose-fermenting bacillus which was serologically specific. A review of the literature is given by Nelson.<sup>1</sup>

*S. paradysenteriae* Sonne apparently may produce both extremely severe and mild cases of dysentery. In acute cases there is a sudden onset with epigastric pain, vomiting, diarrhea, and prostration, and death may result. On the other hand, the patient may recover, after a few days to relapse with the same symptoms. The temperature fluctuates between 100° and 104°. The mild cases do not exhibit particularly abnormal symptoms. The temperature rise is not as high, usually 100°–101°; vomiting and epigastric pain do not usually appear but the patient passes a number of loose, watery stools each day. The mild cases last a week or less. The organism can be recovered without difficulty from the patient's stools during the illness.

In this investigation 9 cases are recorded, 7 of which are from a single family exhibiting both mild and severe types of dysentery. One, 263A, was associated with some 150 other boys in a school in another state, all with a diarrheal disease, a number of similar cases occurring simultaneously in the town in which the school is situated. Since no examinations of feces were made, no epidemiological studies could be carried out. The other case occurred in a hospital in Hart-

\* Read before the Laboratory Section of the American Public Health Association at the Sixtieth Annual Meeting at Montreal, Canada, September 17, 1931.

† Although for convenience the authors use the nomenclature suggested in *Bergey's Manual*, 3d ed., that they do not fully subscribe to his classification of this group of organisms is evident from the context.

ford, and was fatal. The following case reports are included as illustrations of the mild and severe forms of disease encountered.

*Case 1.*<sup>5</sup> B. C., age 4. July 24, 1930, taken suddenly ill with chills and high temperature ( $104^{\circ}$ ). Many loose watery stools streaked with blood. Severe intermittent pains through the abdomen which was tender to pressure without distention or rigidity. After 4 or 5 days, symptoms subsided, temperature came down to normal, and the child felt well. Two weeks later the same sort of illness recurred, with apparent recovery.

This case was typical of the 7 in the family. During August and September all other members of the family came down in turn, frequently 2 at a time. The children were ill more often than the adults.

*Case 2.*<sup>5</sup> R. D., age 16 months, admitted to hospital December 23, 1930. Rectal temperature  $99.4^{\circ}$ . No physical findings of significance. Child appeared well for 7 days; temperature normal. December 30, rectal temperature  $100.2^{\circ}$ , and child somewhat restless. Had several rather loose yellowish stools and was cross and irritable. There was a slight nasal discharge and a slight infrequent cough. The temperature rose rapidly to  $103^{\circ}$  and during the night 7 loose, yellowish evacuations showing no blood occurred. Temperature remained high, and patient died at noon, December 31.

No laboratory examinations were made during acute illness. Previous Wassermann and throat culture had been negative.

Cultures from the tonsillar exudate showed a mixed flora without any pathogenic organisms predominating. Culture from cecum showed *S. paradysenteriae* Sonne predominating organism, a few *Escherichia coli* and fecal streptococci.

A bacteriological and antigenic study has been made of all the cultures isolated since July, 1930, to determine whether they gave consistent reactions in carbohydrate media, to determine differential laboratory tests, and, to study the antigenic relationship of *S. paradysenteriae* Sonne to other members of the paradysentery group.

#### MORPHOLOGICAL CHARACTERISTICS

The isolation of *S. paradysenteriae* Sonne has been fairly simple. One gram of suspected feces was emulsified in 2 to 3 c.c. of isotonic salt solution, and 1 loopful streaked on petri dishes containing suitable media. Both eosin-methylene-blue agar and Endo's medium have been used with equal success. In 24 hours colonies of *S. paradysenteriae* Sonne appeared smooth, greyish white and translucent, 2–3 mm. in diameter, similar to other organisms of the dysentery group in morphology. After 48 hours the following characteristics were noted:

*Eosin-methylene-blue agar*.—Colonies were 0.5 to 3 mm. in diameter, convex and translucent, with crenated edges in the majority. Some cultures had a tendency to produce a slight pale blue center, and some a fecal odor.

*Endo's medium*.—Colonies were smooth, glistening, translucent, raised, with en-

tire edge, in size from 0.5 to 3.5 mm. No fecal odor noted. Crenated edge not observed. The colonies had a bluish tint in direct light, with tendency to develop pale pink centers.

*Agar plates*—Colonies varied from pin points to 4 mm.; with definite crenated edge; white, translucent and raised, with a pale blue tinge in direct light. A fecal odor was present in some cases.

*Agar stroke*—On agar slants the growth was echinulate, glistening, butyrous, raised, translucent, slightly granular under hand lens. The odor was not consistent but fecal when present. Figure I shows the type of growth on eosin-methylene-blue (A), Endo's medium (B), and agar (C).

FIGURE I—*Shigella Paradyenteriae* Sonne on Eosin Methylene Blue, Endo and Agar Media

On microscopic examination the organism appeared as a Gram-negative, short, coliform bacillus with involution forms, the latter 5 or 6 times longer than the short bacilli which predominated.

#### PHYSIOLOGICAL CHARACTERISTICS

A comparison of fermentative ability was made between the cultures isolated and "*Metadysenteroides*" 4086, *S. paradyenteriae* Sonne 31, and *S. dispar* 29, of the American Type Collection. A series of carbohydrates including dextrose, lactose, sucrose, maltose, levulose, mannite, raffinose, salicin, galactose, sorbite, inulin, xylose, arabinose, adonite, inosite and rhamnose was inoculated and readings made daily for 21 days. Andrade's indicator was used in all carbohydrates. The methyl red, Voges-Proskauer, indol and Koser's citrate tests were made. The results are shown in Table I. It will be noted that dextrose, levulose, mannite, galactose, arabinose and rhamnose were fermented within 24 hours, whereas lactose, sucrose, maltose and raffinose were fermented late in the majority of cases. Sucrose seemed the carbohydrate which resisted fermentation longest.

More than one culture was isolated from most patients and these were inoculated into the carbohydrates in duplicate. Although the

\* Cultures obtained from the American Type Culture Collection.

† Exponent designates number of days necessary to produce acid.

‡ Not classified.

final readings were the same, the time varied. For example, cultures 417A and 417B, isolated on different days from the same patient. Culture 417A showed formation of acid in lactose in 1 day and sucrose in 2 days, whereas 417B required 7 and 9 days respectively. These apparent discrepancies, noticeable throughout the investigation, emphasize the necessity of long incubation of these organisms in carbohydrate media.

An examination of duplicate cultures of "*Metadysenteroides*" and of *S. paradysenteriae* Sonne (Table I) indicates that their fermentation reactions are identical, whereas *S. dispar* has different reactions, the latter showing fermentation of sorbito and xylose and producing indol. The fermentative reactions indicate that "*Metadysenteroides*" and *S. paradysenteriae* Sonne are identical organisms, whereas *S. dispar* is quite different. Continued transplantations of the above cultures demonstrated the consistency of these fermentative reactions.

Cultures 165A and 165B were isolated from a case in a family from other members of which typical *S. paradysenteriae* Sonne had previously been isolated. It will be noted (Table I) that their reactions coincide in general with those of *S. dispar*. However, the amount of acid produced in lactose, sucrose, and raffinose was very small, and 20 daily transfers in those 3 sugars failed to increase the acid production. They were found to be serologically different from *S. dispar* (note Table II).

\* Homologous antiserums.

NOTE: Figures represent greatest dilution in which complete agglutination appears.

#### SEROLOGICAL CHARACTERISTICS

Antiserums were prepared with 3 organisms obtained from the American Type Collection, *S. paradysenteriae* Sonne 31, *S. dispar* 29, and "*Metadysenteroides*" 4086, by inoculating rabbits every other day over a period of 20 days with increasing doses of heat killed organisms. Some difficulty encountered with culture 31, was overcome by the use of minute doses of living organisms. The animals, after 24 hours' fasting, were bled from the heart when a titer of approximately 2,500 had been reached.

Agglutination tests were made using the various cultures isolated and those from the American Type Collection. The results are given in Table II. Antigens for all agglutinations were prepared to correspond to a turbidity of 7.6 to 7.8 with the Gates' apparatus. Titers

varying from 1,280 to 2,560 were obtained with all the cultures used except 29 and 165A; the former, *S. dispar*, and the latter a culture isolated from a case of diarrheal disease in a family from which a number of cultures of *S. paradysenteriae* Sonne had been isolated (note 417A and 451).

The cross agglutination between *S. paradysenteriae* Sonne 31 and "*Metadysenteroides*" 4086 would indicate that they are identical. This is corroborated by the reactions of the antisera of these organisms with the cultures isolated in our laboratories.

A Sonne antiserum (Sonne Nelson, Table II) obtained through the courtesy of Dr. R. L. Nelson, of the Infants Hospital, Boston, showed reactions practically identical with those obtained with the Sonne and "*Metadysenteroides*" antisera prepared in our laboratories.

Agglutinations were obtained with antisera prepared with *S. dispar*, with its homologous antigen 1:1,600 and with a strain of *S. paradysenteriae* Flexner 1:150. It was found that a Flexner antiserum (Lederle) was capable of producing agglutination as high as the 1:400 dilution with a culture of *S. dispar* in comparison to 1:1,600 with its homologous antigen. No cross agglutination occurred with Shiga antiserum.

In order to study further the agglutination of *S. dispar* by Flexner antiserum, it was absorbed with Flexner organisms. The absorbed antiserum produced no agglutination with Flexner organisms but continued to give an agglutination of undiminished titer (1:400) with *S. dispar*. The absorption of *dispar* antiserum with its homologous organism produced different results in that no agglutination was obtained with either a *dispar* or a Flexner strain. On absorbing the antiserum with heterologous organisms the *dispar* strain was capable of partially absorbing Flexner agglutinins from the Flexner antiserum although our Flexner strain was incapable of absorbing *dispar* agglutinins from a *dispar* antiserum (Table III).

It was expected on absorbing Flexner antiserum with a Flexner antigen that because of their apparent cross relationship (note column one, Table III) the absorption would deplete materially the titer of the group or heterologous agglutinins, but although all the Flexner agglutinins were absorbed, the titer remained unchanged with the *dispar* strain.

The Flexner antiserum was prepared with 4 strains: (1) Flexner Harris, Rockefeller Institute; (2) Strong, Army Medical Museum; (3) Hiss Y., Army Medical Museum; (4) Flexner, Army Medical Museum. (Personal communication from the manufacturer.)

Since absorption of this antiserum with our single Flexner strain

TABLE III

\* Figures represent complete agglutination.

NOTE: The Flexner antiserum was obtained from Lederle. The dispar antiserum was prepared in our Laboratories with a strain obtained from the American Type Collection.

did not deplete the dispar agglutinins (Table III) the evidence indicated that one or more of the strains used by the manufacturer were multiple antigens, with respect to dispar; i.e., had the ability to produce agglutinins for dispar as well as Flexner. Further, our stock Flexner strain used for absorption is apparently a pure antigenic strain with respect to dispar since it was not able to deplete the dispar agglutinins in the Flexner antiserum although absorbing completely its homologous agglutinins. This is corroborated by absorbing a dispar antiserum with our stock Flexner strain. In this case (Table III) all the Flexner agglutinins were removed whereas the dispar titer remained the same. Since our dispar serum (prepared with *S. dispar*, American Type Collection, showed cross agglutination with our stock Flexner strain, and the dispar organism is capable of depleting Flexner agglutinins in the Flexner serum the evidence indicates that this organism contains a multiple antigen for Flexner. This is corroborated by absorption of dispar serum with its homologous antigen since in this case the agglutinins for both Flexner and dispar were completely removed. The multiplicity of antigen in the Flexner-dispar series is being investigated further.

#### DISCUSSION

Relatively little work has been done in this country on *S. paradysenteriae* Sonne. However, the recent work of Nelson<sup>1</sup> indicated its importance as a cause of diarrheal disease in Boston, and it is the purpose of this investigation to emphasize further that this organism has greater significance as a cause of dysentery than has been suspected. Since mild forms of the disease characterized by diarrhea, headache, and slight abdominal pain with little fever clear up quickly,

it may be that a large majority of cases of diarrheal disease are due to this organism.

We found the laboratory diagnosis comparatively simple. The colonies of *S. paradysenteriae* Sonne are striking on differential media such as eosin-methylene-blue or Endo's medium, and the growth is vigorous on the more common media. The fermentative reactions were consistent and although the time required for a given carbohydrate to be acted upon varied, the end results were identical.

Separation of the Sonne and dispar strains is readily accomplished by their fermentative and serological reactions. No serological relationship was shown between our Flexner and Shiga strains and *S. paradysenteriae* Sonne although a distinct cross agglutination of a Flexner strain and *S. dispar* was demonstrated.

Our results corroborate those of Nelson<sup>1</sup> in that *S. paradysenteriae* Sonne 31, and "*Metadysenteroides*" 4086 described by Castellani, appear to be identical in fermentative and serological reactions whereas *S. dispar* (Andrewes) gave distinctly different reactions.

Cultures 165A and 165B (Table I) have remained unclassified. Although giving reactions consistent with *S. dispar* no serological relationship could be demonstrated. Further work is being done on this organism.

#### SUMMARY

1. Nine cases of diarrheal disease caused by *S. paradysenteriae* Sonne are reported.
2. A detailed, morphological, physiological and serological study is presented.
3. The American Type Collection Cultures *S. paradysenteriae* Sonne 31 and *Metadysenteroides* 4086 appear to be identical in their fermentative and serological reactions.
4. *S. dispar* 29 appears to be distinct from *S. paradysenteriae* Sonne in its serological and fermentative characteristics.
5. A serological relationship between *S. paradysenteriae* Flexner and *S. dispar* is demonstrated by direct agglutination and by agglutinin absorption.
6. Further emphasis is placed on the significance of *S. paradysenteriae* Sonne as a cause of diarrheal disease in this country.

# Health Facts—What to Tell\*

DONALD B. ARMSTRONG, M. D., Sc. D., F. A. P. H. A.

*Third Vice-President, Metropolitan Life Insurance Company, New York, N. Y.*

WHAT to tell—not how to tell it—that is the question. Of course, in the final analysis, what to tell depends in part on whether or not it can actually be made intelligible to the man in the street. Consequently, even from our angle, we cannot altogether ignore the question of application.

In appraising so-called health facts, we want to be certain that they are true and that they are important. But truth is relative, particularly in point of time. What is true for one generation is not true for the next. The evolution of “factuality” is like the evolution of morality. Both are always in transition. That is perhaps why facts, like moral values, are not often pure white or jet black but, to paraphrase the “Old Fra,” usually a rather slaty gray. That is perhaps why in public health as in other movements, it is often easily possible to give an aura of reality to what is mostly fiction.

## VARIETIES OF HEALTH “FACTS”

Yet in the field of health and disease, there are always a few things about which we are quite certain, even though the professor of medicine is accustomed to initiate his first series of lectures with the warning that, in medicine, there are two words rarely applicable; namely, “never” and “always.” In any event, it is certainly true that a consensus of scientific opinion, approaching the data used in health education on a factual basis, would be willing to throw most of the items, legitimately or erroneously used as facts, into several groups:

1. Items in health practice that, certainly for our times and as far as we can see for the future, are scientifically certified facts.

2. Items whose probability is large, but where we are not quite certain of our facts. This group may include items that a previous generation accepted without question, but which we now may be unlearning, so to speak. It may also include a group of near facts that increasing experience seems to make more and more probable, but about which we as yet have no final proof.

3. Items extensively used as facts, especially for commercial exploitation, but

---

\* Read before the Public Health Education Section of the American Public Health Association at the Sixtieth Annual Meeting at Montreal, Canada, September 17, 1931.

which we know either to be erroneous, or at least employed with misleading and perverting aims.

As the field of admitted scientific factual data enlarges and progresses, it acquires in advance of it new facts, as theories and hypotheses are underwritten by investigative verification. In its trail, it sheds once accepted facts into a region of doubt, and may be said always to be acquiring new fallacies for old.

#### NEW FALLACIES FOR OLD

We once, many years ago, wrote an article on the subject of health fallacies, in which attention was paid to "disease germs that lurk in dark and damp places," the alleged dangers of sewer gas, and the excessive proportion of health department budgets that was then spent for plumbing inspection. We also touched upon the exaggerated importance of housing equipment over the more significant items of living methods. In the intervening years, these fallacies have entirely receded into the periphery of doubt and darkness, and no longer require destructive attention. In fact, we may now more usefully attack certain more recently suspected fallacies, such as "the clean tooth never decays," or the myth about underweight as a guide to the detection of tuberculosis in school children. The fallacy of this much respected theory has been brought out very effectively by the work at the Phipps Institute in Philadelphia on tuberculosis among school children. It has perhaps been even more dramatically emphasized in the study of 1,000 supposedly normal adolescent children in the schools in the Bellevue-Yorkville District of New York City. You will remember that of 1,000 children carefully examined with the X-ray, tuberculin test, and the fluoroscope, 184 were placed in what was known as the tuberculous group—not active tuberculosis alone, of course, but latent or grave quiescent lesions, or arrested conditions requiring continued observation and hygienic care. Now, it is significant that among these 1,000 children, there were 128 who were 10 per cent or more underweight, but only 18 of the 184 tuberculous children were in this group of 128. In fact, more tuberculosis was found among the overweight children than among the underweight. Consequently, an alleged health fact tremendously exploited throughout the schools of the world, becomes very nearly, if not quite, a health fallacy.

It is our obligation to discuss health facts rather than health fallacies. Nevertheless, we cannot resist the temptation to cite one additional widely advertised "health fact" that seems in part to be fallacious: the often cited, ever increasing tide of the so-called principal cause of death, namely, heart disease. Is this a reality? Certainly,

the general death rate for all forms of heart disease at all ages has been steadily increasing. Two years ago, for the first time in several years, there was a break in this upward curve, perhaps only temporary, yet worth watching. On the other hand, we must realize that this heart disease picture is made up of 3 principal elements.

First, it includes children and young adults under 45, where deaths from heart disease are a tragedy and a disaster. Perhaps in most cases, the etiological factors here are the acute infections resulting in heart tissue injury. Prevention largely involves the control of these infections. The incidence of these infections, such as diphtheria, scarlet, typhoid, and acute rheumatic fevers, is markedly decreasing, a factor that may be related to another significant observation, the recent very definite decline in heart fatalities at these ages. This, the most important age group sector in the heart disease range, presents a trend that is not only not alarming, but decidedly reassuring and encouraging.

Second, the heart disease picture also includes the age group from 45 to 65 or 70, where deaths from heart disease are certainly unfortunate. It is thought that they result partly from acute infective injuries, but more from syphilis. Prevention means mainly the control of syphilitic infection, and particularly the prevention of the advanced stages of syphilis by detection and adequate treatment. Is it possible materially to affect heart disease mortality in this middle age group by these control measures as well as by personal hygiene, the periodic health examination, or the practice of physiological thrift? That seems probable, so that here too, as well as in the younger age group, the picture is not discouraging.

Third, the heart disease picture includes, of course, the senescent, old-age, degenerative type occurring usually beyond 65 or 70. Deaths from heart disease in this age group are increasing, and are inevitably bound to increase as the population ages, and as larger groups survive to invade this age period. Heart failure is an inevitable incident in this age group. On the other hand, here it certainly is not a tragedy as it is among young adults, nor the unfortunate factor it is in the middle age population element. In fact, it is almost a natural process, and in a great many cases, a benign, beneficent process, furnishing an easy and painless as well as an unprotracted termination of life.

From the point of view of health facts, it is important to distinguish between these 3 elements. To present the general combined death rate from heart disease as an increasing and inevitable menace is obviously misleading and unduly discouraging. The increasing rate is real, but is neither altogether deplorable nor alarming. Furthermore,

it is certainly in part the inevitable and desirable *sequitur* of disease prevention and life prolongation in the earlier age groups. This is a case where analysis and appraisal are essential to the presentation of a true picture for public view, and indeed for constructive, hopeful action.

#### GRADE A FACTS

But let us come to the kernel of our story—to the factors in our health educational program that can today, at least with reasonable confidence, be labelled Grade A facts. Obviously, we cannot attempt to list all of the items that in our opinion could now be classified as Grade A; yet all items employed by health educational agencies in their programs should regularly be scrutinized from this point of view. Here are a few examples of Grade A facts, yet even to these there probably would not be universal acquiescence.

Take the question of diet. There is, of course, a great deal we do not know about nutrition, yet we seem to be quite certain that a balanced ration is of fundamental importance to health. This idea seems to be generously supported both by animal experimentation, and human experience. Dr. Sherman and others have pointed out that apparently for normal life and growth, for disease resistance, and for tissue health, we must have at least a minimum supply of calcium, and possibly other minerals, and of the vitamins, perhaps particularly A, C, and G. Consequently, health education that interprets this point of view of science in practicable and intelligible statements, would seem to be based solidly, for the time being at least, upon health facts.

There seems also to be a high degree of certainty as to the hygienic and therapeutic value of sunlight, within fairly definite limitations. While widely exploited for commercial ends, sunlight, either natural or artificial, seems to be a definite aid to health and strength when properly used. We need here, of course, careful delimitation and definition, but with scientific guidance, there is much that can be said with assurance.

Let us consider communicable disease. There is much that seems to be incontrovertible within the limits of our present knowledge. We have many positive facts concerning the sources and modes of infection. Much has been proved about water and milk supplies as mediums of infection, and about carriers in typhoid fever, diphtheria, and other affections. We can speak with definiteness concerning the importance of protecting infants from contact infection in such diseases as measles and whooping cough. We know that it is important to advocate the washing of hands before eating and after using the toilet. There is much that can be said with assurance to parents con-

cerning the proper care and treatment of, as well as the convalescence from such a disease as measles, not so much to prevent infection, as to prevent complications, serious sequelae, and fatalities. Finally, on the side of prevention, we have very definite facts to offer the public in the field of immunization as applied to diphtheria, smallpox, and typhoid fever, and, with somewhat less positiveness, to measles, scarlet fever, and certain other conditions.

#### FACTS HANDICAPPED BY METHOD

Still in the field of what may be considered Grade A facts, there is a fluctuating volume of health promotive and disease preventive educational items that has, in theory, full scientific support, but whose effective application is handicapped by a serious limitation, or an inherent frailty in method of use; for example, the movement for early disease detection. Much is being said to the public about early diagnosis, and to the medical profession about so-called pre-clinical medicine. The slogan is "Find disease early," and to some extent this is a sound objective. Certainly many affections can be diagnosed, treated, and arrested or cured at a much earlier stage than the usual course of events permits. Examples of this are an incipient tuberculosis, a localized cancerous growth, an early pancreatic, or cardiac, or nephritic affection.

The medium advocated is the periodic health examination—a medium sound in theory, but as yet very frail in practice. The public is not yet educated to go to the doctor early enough; the doctor not yet sufficiently interested or informed or equipped to carry out the requisite examination and tests; and few communities have the necessary machinery to guide the individual to legitimate private or publicly organized sources of such service. Hence, the machinery for applying perfectly good health facts is, in this instance, very defective, and still constitutes a serious handicap upon what is theoretically a perfectly reasonable program.

Of course, the periodic health examination movement comes in for considerable criticism, not only from the lay public on the grounds of inadequate execution, but also from the professional side. It has been claimed by prominent authorities that the possibilities of early disease detection have been grossly exaggerated, which may to some extent be true. Undoubtedly, here our health facts are not quite so absolute as we should like to have them. It is also claimed that this health examination movement has certain very distinct psychological disadvantages; that it places too much emphasis upon physical welfare and physical symptoms; that it excites too much curiosity, fright, and in-

tropection; that it causes as much harm through worry as it does good; that it is, in other words, injuriously and often disastrously suggestive.

On which side of this argument does fact lie? It is no doubt true that most of us are open to influence by suggestion, but the principal question seems to be, where shall we get our suggestions? Shall they come to us from a scientific source through the physician on a basis of knowledge and fact, or through quackery, backfence gossip, patent medicine advertisements, and the ignorant imaginings of uninformed minds? It would seem that the former alternative is preferable, and is on the factual side. If that is true, we should teach the public not to be afraid of facts. Facts should furnish a relief from unfounded fears, and afford an opportunity to face genuine dangers intelligently.

In this general health educational movement for early disease detection via the health examination, it is important to be sure as to what diseases are detectable in their incipency, and to what degree—certainties which we do not as yet possess. It is equally important to recognize that in this movement we are very decidedly limited by method, and that our educational program should not step too far in advance of the development of assured technical and clinical procedure. Yet facts there are, and worthy of constructive if conservative use.

Incidentally, it should also be recognized that there are some health facts that are not applicable for general public dissemination. Not all facts are for all people at the same time. While it is highly desirable to reach all mothers with a message on diphtheria immunization, for instance, it is not necessary to tell all mothers, with the same force and authority, about the use of convalescent serum or whole blood for the prevention of measles, or its complications. It may be desirable, in a still more limited way, to be able to instruct a few people in certain of the health facts concerning personal hygiene, not in large groups, but perhaps even individually through the physician or health adviser. Here again, it is not so much the facts that are lacking as the machinery.

There should exist in every community the facilities for individual medical and health guidance. General broadcasts by radio, through literature, the press, advertisements, and all the wholesale devices available, will not serve to answer intimate personal questions on health and disease prevention. The private physician should eventually fit in here most effectively. In the meantime, people are seeking this kind of individual advice, and it is only through the development in communities of facilities for individual medical and health guidance, preferably, to my mind, under the auspices of county medical societies, that this need can be met. Only in this way can our store of health knowledge, whatever its limitations, be utilized to the full.

## THEORY VERSUS PRACTICE

We have cited examples of facts that are applicable in theory, but not always in practice, owing to difficulties of procedure. This aspect of the problem may be illustrated from still another angle. Back in 1904 or 1905, when the first tuberculosis organizations were formed, and when health and medical organizations were just beginning to anticipate the possibilities of the application of bacteriological knowledge of the cause of this disease, health propagandists aroused unusual enthusiasm concerning the early control and eradication of this great cause of sickness and death. About 1908 a slogan was adopted in an eastern state, "No Tuberculosis by 1915." Of course, everyone knew that this probably could not be attained, but it served a valuable purpose by emphasizing the theoretically attainable goal. In 1925, or shortly after, another slogan was adopted: "No Diphtheria by 1930." This was another commendable manifestation of hitching a wagon to a star. Goals, after all, are to be striven for, not always to be attained. "El Dorado lies always over the next hill." Up to the present, this method of featuring a theoretical health fact has had remarkable educational advantages, and has certainly furthered the ultimate attainment of the objective.

We should perhaps, from this point on, be somewhat on our guard with programs of this type. While they have been almost wholly advantageous in the past, may they not present a hazard for the future? Should we not be more cautious in our popularized forecasts? It is true that the public memory is short. It may become enthusiastic about the objective, sympathize with the methods, give generous financial and moral support, and then readily ignore the fact that the goal was after all not reached. Yet is it not possible that if we prod this frail public memory too frequently with repeated reminders of failure, not only through time limit slogans, but also through explosive health campaigns, health weeks, and similar concentrations, where the promise is not and almost always cannot be fulfilled, are we not apt to arouse a disquieting and disillusioning train of recollections in the public—a circumstance that would certainly produce a diminishing return in coöperation, or perhaps even a repudiation of leadership? Of course, the public responds more to slogans than to a scientific statement of probability; so we are handicapped in all of our work in this field by the necessity for simplicity.

It is evidently necessary to be assertive and dogmatic. However, there is some admitted hokum in our health educational program, and the public is in a debunking mood. Let us therefore keep, so far as possible, within the realm of the attainable in our prognoses as to the efficacy of our programs.

## GRADE B—NEAR FACTS

Thus far, except for our earlier discussion of new and old fallacies, and of the general region of doubt which surrounds the factual health field, we have been discussing Grade A facts—things which we think are almost if not certainly true, but which may be seriously limited in their application for the reasons cited. In the health educational field, as we implied in the beginning, there is another, even larger, body of very appealing items—things which we generally believe to be true, which we would very much like to have true, but which, in the majority of instances, we cannot actually prove. One can pick up almost any health publication from any legitimate agency, official or private, and find examples of this type of health statement.

I have before me at present a bulletin of an official department in Washington. It contains a list of rules for health. One is: "Drink at least 4 glasses of water a day." Sometimes this rule reads 6, and sometimes 8 glasses a day. This sounds like good advice, but have you ever attempted to verify it on a basis of scientific experiment, except perhaps for certain pathological conditions, such as a case of nephrolithiasis?

Another bulletin, from a very responsible organization, states that practically everyone needs an average of 8 hours' sleep every night. This we have found somewhat difficult to verify. Then, take fresh air—how frequently have you read and also said that fresh air prevents colds, and "catching" diseases like tuberculosis? What do we really know about colds, for instance, in this connection? Then, exercise—"There is no better way to prolong life." Of course, there is no better way to shorten life for some people, and there are a great many people who live long and happily who take very little if any exercise. It is undoubtedly a good general health rule, but the scientific background for it is extremely vague compared with the fact, for instance, that vaccination prevents smallpox.

Then, cleanliness—"Full bath more than once a week." What health condition will that promote? what disease will it prevent? how will it prolong life? The cold shower—does it prevent colds by "hardening the skin"? Has it really any relationship at all to colds? Certainly, cleanliness is esthetically and socially desirable, and the cold bath is a pleasant, invigorating habit for many people, but how do these compare as facts in contrast to the certainty with which vitamin D will prevent rickets, or to the assurance with which we can guarantee protection against diphtheria with toxin-antitoxin or toxoid? How important is it to "Brush your teeth twice a day" in order to prevent dental caries, as compared with the significance of an adequate supply

of calcium and vitamins A and C in the diet? Presumably, we also have near facts in the immunization and related fields, such as the Calmette vaccine for tuberculosis, the use of convalescent serum in the treatment of poliomyelitis, etc.

Numerous other examples might be cited. Yet it remains that these near facts are appealing, and convincing. In general, we all feel that their promulgation does some good and little if any harm. We feel that most of them are in the right direction though they need verification, and subsequent experience may slightly or extensively modify our views. Here again, of course, we suffer from the necessity of health education being direct, simple, and dogmatic.

#### CURRENT APPRAISAL DESIRABLE

It may not be inappropriate to suggest the advisability of creating in this organization, and in this section, a committee or other piece of machinery for a comprehensive and continuing review of all of the data that we find appealing and apparently useful in health education. This would mean a careful analysis of the multitude of statements that appear with official or other reliable endorsement. It should also include statements that appear through the spurious channels of quackery and through misleading commercial exploitation. Such an appraisal would lead perhaps to a classification that would be subject to appropriate publicity, as well as to periodic revision. The objective of such a program would be the allocation of facts and their more doubtful relatives into certain groups, on a basis of soundness, of importance, and of timeliness. Of course, importance and timeliness are largely influenced by local conditions and the circumstances of local application. As to soundness, it is believed that these data would almost all, if not all, fall into one of the following groups.

#### I. Assured Health Facts:

- A. Those universally and practically applicable
- B. Those theoretically sound but limited in application because of the imperfections in available methods or for other reasons

#### II. Near Facts:

- A. Those about which there is a growing certainty, though as yet no absolute scientific assurance
- B. Those once generally accepted but about which there is an increasing element of doubt

#### III. Assured Health Fallacies

A study and classification of this type should furnish a valuable guide to health officers, medical societies, and especially teachers, lay health educators and those social workers and social agencies now so

vitality related to the proper and effective capitalization of verified health data. This suggestion is submitted for the consideration of the section.

#### A BALANCED VIEW

Finally, if we are to be assured of the continued sympathy and support of our public—the recipients of our health educational efforts—it is important to maintain a sane and balanced attitude. We do not need to accept the extreme individualism and pessimism of Hutchison, and other critics of current health educational effort, in order to take advantage of certain constructive points which these critics emphasize. Let us not present health as a matter exclusively of rules and regulations. Let us not present it as something almost impossible of attainment. Let us feature health rather than disease, so far as that is reasonable. Let us not exclusively preach health for health's sake, but remember that health after all is a means and not an end, and is to be striven for, or at any rate respected, as a basis for growth, character, service, and happiness. In influencing those whom we instruct, let us endeavor to avoid the creation of self-conscious, fear ridden, health prigs, who go by rote and timidly about their daily tasks, with germ-catching respirator and antiseptic mouth wash ever at hand. Let us rather aim at the development of health informed, intelligent, and courageous adventurers in life.

---

### Recent Child Welfare Measures in Spain

THE Government of Catalonia, Spain, decided to send 4 teachers to England, Austria, and Belgium for a 3-month study of kindergartens in those countries. It intends to establish kindergartens and day centers for children of school age whose parents are employed outside of their homes.

Education of defective children is receiving a great amount of attention in Spain. The Institute of Mental Education, a private organization interested in the education of retarded children, has sent an appeal to all members of the National Legislature of Spain, asking them to make satisfactory provision for the education of mentally defective children. At the same time the Spanish League for School Hygiene decided to present to the Minister of Public Instruction a memorandum on the essential points of school hygiene, which, in the opinion of the League, should be included in the public education law that is expected to be enacted before long.—*Maternità ed Infanzia*, Rome, Nov., 1931, p. 1212.

# Incidence of Tuberculosis in the Industrial Population \*

LOUIS I. DUBLIN, PH.D., F. A. P. H. A. (*Life Member*)

*Third Vice-President and Statistician, Metropolitan Life Insurance Company, New York, N. Y.*

FOR a long time, it has been realized by those who have studied the tuberculosis problem that the disease is not uniformly distributed in the population as a cause of sickness and of death, but that it is concentrated in certain strata and groups. In fact, the campaign to control the disease is more and more directing its attention to these classes and groups. Common observation and everyday experience have shown that tuberculosis is much more prevalent in the industrial population of the country than in the agricultural, the commercial, or in the professional trades. It is the purpose of this paper to point out certain variations in the tuberculosis death rate in the various elements which compose the industrial population. This should prove to be an important aid to the movement against tuberculosis, as it will show where the disease takes the heaviest toll of life, and where it is less prevalent. Such knowledge should make it possible to economize effort and to concentrate resources where they will do the most good.

By the industrial population I mean that large section of the people who live, for the most part, in the cities and towns, and who draw their support from employment in the industries of the country. They are, almost altogether, wage earners and their dependents, including women and children. I use this term "wage earners," knowing well its limitations, to identify the group I shall discuss with that large number of people who are insured in the industrial insurance companies of the country. I might have entitled this paper with more propriety, "The Incidence of Tuberculosis among Those Insured in the Industrial Department of the Metropolitan Life Insurance Company." The advantages gained by using this material are many. It covers a period of 20 years; relates to a population extending over the states and provinces of the United States and Canada; and includes millions of negroes as well as white persons—virtually all city dwellers who live on wages.

---

\* Read at a Joint Session of the Vital Statistics and Epidemiology Sections of the American Public Health Association at the Sixtieth Annual Meeting at Montreal, Canada, September 16, 1931.

Tuberculosis is primarily a disease of the working classes of the country. In 1930, for example, the death rate from all forms of tuberculous disease, among the industrial policy holders of the Metropolitan, was 81.3 per 100,000. In contrast, the death rate for the ordinary policy holders for that year was only 48.7 per 100,000.

These ordinary policy holders are persons who carry insurance ranging from a minimum of \$1,000 up to hundreds of thousands of dollars. In the Metropolitan, a great many of the ordinary policy holders carry industrial insurance also. The ordinary department death rate for tuberculosis would be lower still if these were excluded. For example, among those who carry insurance in policies for \$5,000 or more (among whom very few carry industrial insurance), the rate was only 17 per 100,000; and among the many employees of the company the rate was 40 per 100,000. It is clear, therefore, that the two main classes of the population are sufficiently far apart in their tuberculosis death rate to show how important is the industrial factor.

We may still further drive home this contrast by recording the fact that the death rate from tuberculosis in the general population of the U. S. Registration Area for the last year available, 1929, was 76 per 100,000 of population, as compared with 87 for wage earners and their dependents. But this figure (76) includes deaths from tuberculosis in the industrial population, as well as in all of the rest. If it were possible (which unfortunately it is not) to obtain the death rate from tuberculosis for the entire population, outside of the industrial class, the rate would be considerably lower than 76. A closer approximation, perhaps, to the tuberculosis death rate of the non-industrial population is the rate for 1929 for the rural area of the United States. That death rate was 74.7 per 100,000,\* but even this figure is much higher than the true rate for actual, permanent residents of the rural districts, because it includes that large number of deaths of city residents who went to rural communities in search of health, and died there either in sanatoriums, hospitals, or in private homes.

There can be no question, in view of these figures, of the heavy concentration of tuberculosis as a cause of death in the urban industrial group of the population. Every refinement we could make, which would separate out those who work for salary, or on farms, from those who work for wages in industrial establishments, would make the distinction all the greater. I do not for a moment suggest that tuberculosis is not an important factor in the mortality of the farming population, or that it does not strike down others than the industrial workers in cities; but it does this more infrequently.

\* When general population death rates for 1930 become available a still lower rate will be shown, and a greater contrast with the 1930 rate for the industrial policy holders, 81.3.

TABLE I

DEATH RATES PER 100,000 FROM TUBERCULOSIS—ALL FORMS. BY RACE, SEX AND AGE PERIODS.

It is safe to say at this time that, by and large, tuberculosis is rapidly becoming a minor cause of death in all but the industrial classes of the population. We shall later call attention to a few apparent exceptions to this statement. But, to illustrate the essential truth of what I am saying, it is only necessary to note the tuberculosis death rates in 1929 of 27 for the State of Utah; 32 for Nebraska; 33 for Iowa; 34 for Wyoming; 35 for North Dakota; and 37 for Idaho and Kansas. In these states, there is a total population of 7,589,190, of whom about two-thirds (63.4 per cent) are rural dwellers, and only a small percentage may be classified as in the industrial population. In these states certainly it may be said that tuberculosis has already become a minor cause of death.

It would be misleading, however, if we did not call attention to the tremendous improvement that has occurred in the incidence of tuberculosis in the industrial population during the last 20 years. In fact, the improvement has been greater in the industrial classes than in the nation as a whole, or in any other major group of the population; for we find, as between 1911 and 1930, a decline in the mortality from tuberculosis of 64 per cent. In other words, for every 10 lives lost on account of tuberculosis in 1911, only 4 were lost in 1930. In the general population, the reduction in 1929, as compared with 1911, was only 52 per cent. Again, I wish it were possible to indicate the decline in other specific population groups, but the only other one for which data are available is a constantly increasing rural area, which between 1910 and 1929 shows a decline of 41 per cent. Obviously, the disease we are discussing was a much more important factor in the life of all elements of the population 20 years ago than it is now; but this applies particularly to the industrial classes. Yet tuberculosis is still the third cause of death in the industrial and the seventh in the general as well as in the rural population.

Within the industrial classification, the disease will be found concentrated primarily among males and among colored persons. Taking the figures for 1930 for insured white persons as our guide, we find no significant difference between the sexes under age 10. From ages 10 to 15, however, the mortality among females is higher by more than 75 per cent; and between 15 and 20 it is twice as high among white females as among males. Between 20 and 25, it is still 35 per cent higher among white females; but after age 25, the rate is uniformly lower among females; and at the age period 45 to 54 it is only one-third as high. Figure I\* shows the relative importance of the disease

\* The three charts used in this paper are similar in form to those prepared by Miss Jessamine S. Whitney, Statistician, National Tuberculosis Association, for her "Facts and Figures about Tuberculosis." The charts have been brought up to date.

FIGURE I

as a cause of death, in 1930, in the two sexes of the white classification.

Uniformly, the colored people show higher rates than the whites. At some of the younger ages, the rates for the colored are from 5 to 9 times as high as those for the whites, although after age 35 they are less than twice as high for males. Toward old age, the differences become less marked. Table I shows the contrast between white and colored persons on the basis of the 1930 mortality experience in the Metropolitan's industrial department.

With the colored, as with the white, there is substantially no difference under 10 years in the mortality rates of the sexes. Between 10 and 20 the rates for females run from 50 to nearly 70 per cent higher than for males, instead of 100 per cent higher, as they do in the case of the whites. With the colored, it is not until age 35 is reached that the death rate for males exceeds that of females, whereas this condition obtains from age 25 with the whites.

Occupation plays an important part in the incidence of tuberculosis and in its mortality. The very highest rates for the disease are found among those exposed to silica dust. Included here are a large number of workers in ore mills and mines (except coal mines), in the

building industries, and among grinders and buffers, stone workers, pottery workers, employees of foundries and other metal industries, and of the clay and glass industries. Another group having a high death rate from tuberculosis includes those employed in low grade occupations, more particularly common laborers in a variety of industries, longshoremen, porters, freight handlers, watchmen, hucksters, and peddlers.

Certain types of factory work have long been associated with high death rates from tuberculosis, although the mortality among these employees does not reach the figures for those exposed to silica dust. Included among these are the cigar and tobacco workers, shoe factory operatives, those engaged in certain textile occupations, and to a lesser extent workers in the printing trade.

Again, there are a number of occupations, in which there is more or less exposure to organic dust, and which show high mortality from tuberculosis. Among these are barbers and hairdressers, furniture and other wood workers, bakers, textile mill workers, hatters and hat workers (both wool and fur felt), and cigar makers and tobacco workers. The last named occupation has long been recognized as one with an especially high incidence of tuberculosis. In addition to the dust hazard, there is exposure to nicotine and often to general insanitary conditions in the workshops. But it is necessary to point out that in this industry wages are low, and the work attracts many men of poor physique and low resistance.

Another group in which tuberculosis takes a large death toll is laundry workers. This may be due, in part, to the fact that these workers are sometimes exposed to infected material; but the chief factor in their high mortality is probably the conditions of heat and humidity in which they work.

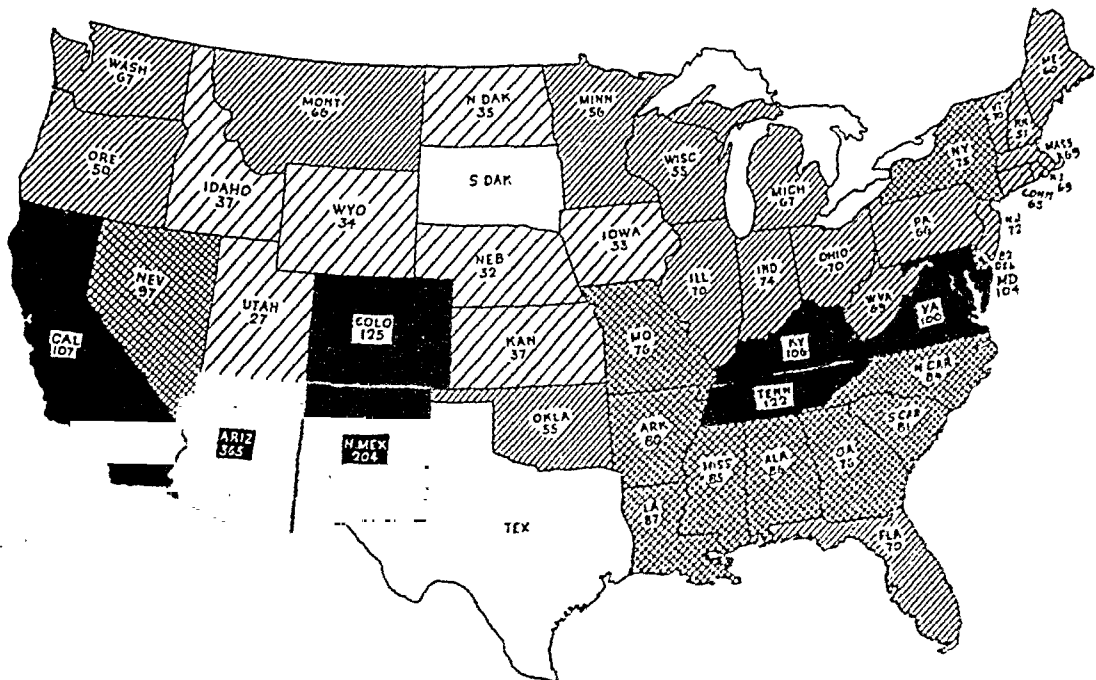

There are other employments in which there is a relatively high incidence of tuberculosis, although they are not associated with any definite industrial risk. Among these are tailors and other clothing workers, cobblers, and slaughter and packing house employees. Clerical workers and bookkeepers also have a higher than average incidence. Here the factors of confinement, poor ventilation, and fatigue, undoubtedly play their part in reducing resistance to infection.

This paper should not close without a brief reference to the geographical aspects of the mortality from tuberculosis. For this purpose I shall have to use data for the general population, even though this paper's title would seem to restrict my discussion to the industrial population. I have already referred to the extremely low mortality in the general population for certain states with predominantly rural.

and non-industrial populations, in order to contrast their low tuberculosis death rates with those of states where the people are more or less concentrated in the cities—and are largely wage earners.

First of all, it will be necessary to disregard the figures for certain states, like California, Colorado, New Mexico, and Arizona, which have very high tuberculosis death rates, solely because thousands of tuberculous people go there every year in the hope that favorable climatic conditions will arrest the disease. Many of these people die each year and thus swell the mortality rates for these states to a point many times in excess of the figure for the permanent residents. There are, however, 4 states where the ravages of tuberculosis are worse than in any others, namely, Tennessee, Kentucky, Maryland, and Virginia. This applies, with the exception of Virginia, to both the white and colored populations. Aside from these states, the following (in addition to the "cure seeker" states) have tuberculosis death rates in excess of the average: Alabama, Arkansas, Delaware, Louisiana, Mississippi, Nevada, North Carolina, and South Carolina.

Figures II and III show graphically the tuberculosis mortality rates in the several states, in 1929, together with the per cent decline in that year, as compared with 1920 for each state. The map shows the 8 "black spots," states in which the tuberculosis death rate in 1929 ranged from 100 per 100,000 up. As noted previously, the high mortality in Arizona, New Mexico, Colorado, and California is due to deaths of non-residents, and the most serious situation prevails in Tennessee, Kentucky, Maryland, and Virginia. In the last named, the tuberculosis death rate among the white population is not far from the average figure for whites in the United States. Negroes, however, constitute 27 per cent of Virginia's population; and their excessive mortality from tuberculosis raises the death rate for the state to one of the highest figures in the entire country. In Maryland, too, the problem is largely with the negroes, although the mortality from tuberculosis among the whites is also above the average.

If it were possible to obtain resident death rates for tuberculosis for each of the states the shadings in the map would be changed in several instances. I strongly suspect, for example, that the figures for Nevada and North Carolina would be materially lower if deaths of non-residents were excluded.

In Figure III, attention is directed in particular to the per cent declines for the several states. It is encouraging to note that no state fails to show a lower tuberculosis death rate in 1929 than in 1920; but one is immediately impressed with the fact that for each of the 4 states where the situation is the gravest, the drop in the death rate has been less than the average decrease in the United States (expanding registration area).

Large cities whose tuberculosis mortality in 1929 was in excess of the average for all cities in the registration states, considered as a group, are: Albany, Atlanta, Baltimore, Birmingham, Boston, Buffalo, Chattanooga, Cincinnati (very high), Cleveland, Columbus, Denver (due entirely to tubercular transients from other states), Detroit, Duluth, El Paso (for the same reason as Denver), Fall River, Houston, Indianapolis, Jacksonville, Kansas City, Kansas, Kansas City, Missouri, Knoxville, Los Angeles (for the same reason as Denver), Memphis (very high), Nashville (very high), Newark, New Bedford, New Orleans (very high), Manhattan and Richmond Boroughs of New York City, Norfolk, Philadelphia, Richmond, San Diego, St. Louis, San Antonio (very high—probably from non-resident deaths), San Francisco, Scranton, Toledo, Trenton, Washington (due to an extremely high rate among negroes—the mortality is not high among whites), and Worcester.

I have, also, comparable data to show the relative mortality from tuberculosis among the insured Canadian wage earning population, as compared with the death rate in the same group in the United States. The figures for Canada are based upon the mortality experience of about 1¼ millions of industrial policy holders of the Metropolitan Life Insurance Company. They relate to a period of 6 years.

TABLE II

DEATH RATES PER 100,000 FROM TUBERCULOSIS (ALL FORMS) AMONG INDUSTRIAL POLICY HOLDERS IN THE UNITED STATES AND CANADA COMPARED

Year	Death Rates per 100,000			Per cent Excess Canada over United States (White)
	United States		Canada (Total Persons)	
	Total Persons	White		
1930	79.7	59.0	97.3	64.9
1929	86.2	64.9	96.8	49.2
1928	89.8	68.4	94.3	37.9
1927	93.0	71.7	100.9	40.7
1926	98.8	77.6	102.5	32.1
1925	97.7	78.4	104.1	32.8

It will be seen, first of all, that the tuberculosis death rate runs uniformly higher in Canada. Furthermore, the decline has been small in recent years, by no means matching the improvement in the United States. Even when we include the mortality among almost 2½ millions of negro policy holders (as we do in the first column of this table), the Canadian death rate exceeds that for the United States; and it must be borne in mind that the tuberculosis mortality rate for negroes runs about three and one-half times that for the whites. As the Metropolitan has comparatively no negroes at risk in Canada, the really significant comparison is that with the insured whites in the United States. There is a wide gap between the Canadian and United States figures. As a matter of fact, with the slow decline in Canada and the abrupt drop in the United States the excess in the Canadian tuberculosis death rate is becoming greater every year. These figures, it must be remembered, relate almost exclusively to city dwellers. Canada's relatively unfavorable record is due entirely to the very high death rates in the industrial populations of the cities in Quebec, Nova Scotia, and New Brunswick. For the remaining five provinces, the mortality from this disease is well below the average for white wage earners in the United States.

On what elements of the population, then, should the attack on tuberculosis be concentrated from now on? First of all, upon the wage

earners in American and Canadian industries, and their dependents. In this group, despite the splendid progress that has been made, tuberculosis still ranks third among the causes of death. Thus, where the greatest progress has been made lies a great opportunity for further progress. Within this wage earning element, the concentration should be primarily on males, except between the ages of 10 and 25, where the mortality among females runs from 14 per cent to more than 100 per cent higher. Second, upon the negroes, both in the industrial and general population, where the reduction in the mortality rate has by no means kept pace with that among the whites—more especially within the last 10 years. Here probably lies the greatest opportunity of all, especially in the age groups under 25, where the negro death rate exceeds the white by from four- to almost ten-fold. Third (and this lies within the field of the industrial hygienist), among those engaged in the several occupations I have mentioned—more particularly among those exposed to silica dust. Fourth, in the general population, both white and colored, of Tennessee and Kentucky, and to a lesser extent in other states, mostly in the South, where the tuberculosis death rate runs above the average; also among the populations of over 30 cities. Fifth, among industrial wage workers and their dependents in the cities of the Canadian provinces of Quebec, Nova Scotia, and New Brunswick.

There is every reason to believe that if the health officers and health agencies of the United States and Canada would concentrate their efforts on these groups of the population, a very definite reduction in both cases and deaths would result. Up to the present time, even lacking such particular concentration of effort, the death rate has declined each year among the industrial population. It should be possible, without undue expenditures of money, to increase the rate of decline. The important thing to do is to concentrate the energy and intelligence of the medical and public health services of the communities along the lines I have indicated. The immediate goal of the tuberculosis movement should be to accomplish for the industrial population what has apparently been brought to pass for those who are somewhat more advantageously placed socially and economically. This can and will be done.

NOTE: Other papers from the symposium on tuberculosis will appear in subsequent issues of the JOURNAL.

# What Is Health News?\*

GEORGE F. WRIGHT

*Editor, Montreal Star, Montreal, Canada*

THE putting forward of such a question as "What is Health News?" opens up a far wider range than would appear at first, for I take it that it is not only a question of what is or is not health news, but how such news can be most attractively and most persuasively transmitted from its source to the general public. That is to say, it is not only a question of health news in itself but of the vehicle, and the machinery of transmission as well. How can health news be presented in its most attractive form so that, in the language of the stage, those who present it will be able to "get it across the foot-lights"?

First, I think it is essential, in so far as the newspapers are concerned, that the copy submitted to them should be arranged and written by a newspaper man, that is, one who is skilled in the craft of journalism. I know that there is a very prevalent opinion that anyone can write stories for the newspapers and that anyone with ordinary common sense can edit a newspaper. I have not occupied the editorial chair for several years without having this forcibly thrust upon me many times. Scarcely a day passes but some male or female applicant for a position, plus salary—always plus salary—approaches me with a request for employment. When I pose to them the obvious question, "Have you had any experience in newspaper work?" they almost invariably reply, "No, but I have always felt that I would like to write for the newspapers and I once wrote a letter to the editor that was printed." Sometimes they vary this by saying they used to write for the school magazine, or they have had friends, or relatives who have been employed on newspapers at various times.

It has often struck me that these same people would never think of going to a doctor and saying that they have always been interested in operations for appendicitis or tracheotomy, and although they had no experience in surgery and no knowledge of anatomy they were simply burning to hold scalpel and forceps in their hands. Nor would they

\* Read before the Public Health Education Section of the American Public Health Association at the Sixtieth Annual Meeting at Montreal, Canada, September 17, 1931.

go to an engineer and express their admiration of the beauty of a steel skeleton skyscraper and suggest that, as they had walked past so many of these buildings and looked with envy on them so often, they might be employed to erect one. I do not believe that doctors, lawyers, engineers, dentists, or other professional men are so plagued; but I am convinced that there is a very widespread belief that the newspaper craft can be learned overnight, and that the will to succeed is more than half the battle.

May I, before this gathering of men of brains and culture, do my bit toward dissipating this error. The newspaper profession requires just as much brains, and just as much training, and just as great native gifts, and just as much genius, as any other profession. I know that the universities neglect this field of training, but that does not imply that the years of training should not be long and arduous. Good newspapermen, like great poets, may be born and not made, but they must pass through a long course in human experience and undergo an exhaustive training before they are competent to be entered as journeymen in this great craft. If, in the process of apprenticeship, they have starved and suffered from cold and had no place to lay their heads and been buffeted by the world, but have won through, they are all the better for the process of sublimation.

May I, therefore, make my first point—that the organization, or individual, the association, the company, or the professor, who wants to get his health news across, should engage a man trained in the art of journalism for that work. The journalist will not only prepare the material in the most suitable form for publication, but if he has had proper training he will know where to place his output and how to adapt its form to the individual requirements of the various newspapers, or the idiosyncracies of different editors.

If I may venture a little further, I might in all humbleness advise the newspaper man who has the preparation of that copy in hand to make his stories short and divide them into paragraphs of different sizes. The make-up man of a newspaper often finds it necessary at a moment's notice to discover a readable paragraph, or even a short sentence, which will fit into an obstinate corner. If such matter is available, it stands a good chance of being used, even if, on its own intrinsic merits, it might not have readily passed a censorious editor.

Next, with regard to the content of the news, medical men as a whole are loath to give publicity to their achievements, their discoveries and their researches. It is not so much, as a rule, that they shun the publicity, but that they fear their findings, which are to them something so intimate and personal as to become almost sacred, may

distorted in the presentation. They charge the newspaper with sensationalism and some mysterious quality which they call yellow journalism, if it endeavors to present a dull, abstruse, scientific subject in popular fashion. They seem to have a rooted objection to the presentation of their researches and discoveries in attractive form.

These same men, in telling clubroom stories to one another, would not hesitate to dress the facts of the story up so that they could hold the interest of those who heard them. A man who tells a story which commands general approval, and wins for the teller a reputation as a good fellow, is the man who presents his story to his listeners in a fashion that rivets their attention, excites their interest, and moves them to tears or laughter. This is exactly what happens when facts are presented to the newspaper man. He sifts the mass of indigestible facts and pounces upon the one that contains real human interest, and dresses his story up to make it readable. He is instantly accused of having given undue prominence to what was a minor fact of the great discovery and he is told that it should be presented in a methodical and orderly fashion which is immeasurably dull and would never induce anyone to read it.

If public health news is to be read by the general public, it must be presented in attractive and readable form, even at the expense of treading on the corns of the erudite professors who are primarily responsible for the sources from which the news originated. I do not mean to say for a moment that the newspaper should sacrifice accuracy and truth. A strict adherence to fact is the one motto which the editor is always placing before his staff. Contrary to the general belief, he does not incite them to such high imaginative flights that they soar far beyond the realms of truth and reality. He knows they have the imagination and he urges them in season and out of season to keep their feet on the ground of realism and truth, when their wings are itching to be spread in an upward and forward flight. But, conforming to the truth and the facts of the case, the newspaper article should be attractive in presentation.

Remember that the standard of intelligence of the newspaper reader is not the standard of intelligence of the university faculties. Out of every 1,000 readers of a newspaper 50 per cent would not gain passmarks in the simplest general knowledge test, so that the newspaper which persistently printed scientific and erudite articles would get a reputation for being "highbrow" which would damn its circulation.

So far as public health news is concerned, there are certain things to be remembered. The people as a whole are receptive to the idea of

health improvements. They are "sold" on the idea of public health, and the thing the newspaper has to do is to show the practical and definite steps that the readers must individually take to bring about a general improvement in public health. That is, readers like to see statistics showing that the death rate is being lowered year after year, and that some of the dread diseases are being conquered, but that type of reading alone will not advance the cause of public health one iota. What the reader has to do is to get into his brain the necessity of carrying out certain simple rules of living. The newspaper must impress this day after day, not openly with the broad sword, but with the finer thrust and parry of the rapier. The direct attack is not always the most effective. To tell people they are dirty and unhealthy will not accomplish the end of the public health teacher half so effectively as to inculcate into the individual the need of more soap and less foul air. The appeal may seem to be to the masses, but its reception is really felt individually.

Constant reiteration of plain truths is of value, but if that plain truth can be garnished and served up in a hundred different forms, as a clever chef might serve the humble potato, the work of the public health officer will be immeasurably lightened.

In conclusion, let me say that editors as a rule are willing to support efforts toward improvement of the public health by giving freely of their advice, their time, and the space in their newspapers. I would be ashamed to measure the prestige which a newspaper receives by the part it plays in fights against the common enemies, dirt and disease. I know that I am very proud to have been associated, in a very humble way, with the fight the *Montreal Star* has made for pure milk and for better health conditions, indeed prouder of this than of any other accomplishment as an editor.

Newspapers want your coöperation. It is your responsibility to obtain that coöperation, each in his own community.

---

THERE has never been any inflation of public health service and it is, therefore, incapable of deflation. Furthermore, public health work has paid its way, being in fact one of the greatest investment services of our people. What we have put into public health has been paid back to the public many times over in reduced sickness and lower medical costs, and in the salvage of valuable lives. Fortunately, throughout the year and, in fact, throughout the period of economic disturbance through which we are now going, the public health has held up beautifully, showing the effectiveness of our health organizations. They may be relied upon even in periods of stress to do their work well."—Louis I. Dublin, Ph.D.

## LUEBECK DISASTER

IT will be remembered that after the administration of Calmette vaccine for tuberculosis at Luebeck, Germany, a large number of the children became ill, the final result being that 68 of 76 children died of tuberculosis.

The work was under the charge of Professor George Deycke. On October 12, 1931, he and those who had assisted him were put on trial with the result that he was found guilty and sentenced to 2 years in prison while Professor Altstaedt was found guilty of homicide and sentenced to 15 months in prison.

Needless to say the affair caused intense distress throughout the world. Professor Calmette sent cultures of the same batch of vaccine to South American and other places, all of which were used without any ill effects. Altogether upward of a million children have been treated with this vaccine without any ill effects as far as has been observed.

It is perhaps needless to add that during the 4 months of this trial every available bit of evidence has been brought forward. The scientific side has been thoroughly discussed. Many scientific men have tested this vaccine on animals and on a number of children. In New York City the Department of Health has used it apparently with excellent results and certainly no ill effects. Two points which have arisen are: (1) that an error was made and virulent tubercle bacilli

were used instead of the attenuated vaccine; (2) that a different culture made from that advised by Professor Calmette was employed and that the vaccine reverted to the virulent type. The conclusion arrived at is that the hospital laboratory was not fitted for such work.

Cultures of tubercle bacilli and Calmette's vaccine were made side by side and it appears that one was accidentally substituted for the other and that these poor children received inoculations with virulent human cultures.

This conclusion seems justified in view of the large number of children inoculated in various countries with Calmette's vaccine without ill effect.

One cannot but feel the utmost sympathy with Professor Deycke and his assistants. Apparently at the beginning he became somewhat hysterical and destroyed some of the evidence. Later he showed himself to be a man as well as a scientist and declared that whatever mistake had been made he was responsible for it. The sympathy of all scientific men goes out to him. Sanitarians and laboratory men will be glad to know that the Calmette vaccine is not dangerous and that this disaster was due to an accident entirely unconnected with the vaccine dose.

### THE MEDICAL PROFESSION AND PUBLIC HEALTH

THOUGH some of our national bodies are cognizant of the bad effects of the general depression on health work through the discontinuance of activities and the resulting dropping of health workers, medical and other, and though there has been widespread fear of the malnutrition which would almost certainly result, comparatively few people, we believe, have considered the plight of physicians in the present emergency. Not only are they in less demand, since people consult them only when necessary, but the payment of fees has been deplorably cut, and the doctors find themselves hard put to it economically. There has been a large increase in the number of indigent ill and the doctors are expected to carry these, as, we are glad to say, they always have done in the past. At the same time, there has been no let-up in the demands made upon them by legislative bodies, taxation authorities, courts of justice, and similar bodies. The public is rapidly becoming educated to demand the best services, the use of modern methods of diagnosis, involving expensive apparatus, and easy access to fully equipped hospitals.

The education of the public is, in our opinion, all to the good. We

have welcomed the foundations, and recognize the good work which they have done. It is, however, equally sure that these various organizations, many of which have millions at their disposal, have to a certain degree made the lot of the practicing physician hard. Numerous organizations, some under medical control, but probably a greater number under lay control, have been aggressively assuming the direction of medical service along a number of lines. Some of this, like the education of the public, is all right. The average doctor is not a good business man. The calls on him are to heal the sick and relieve suffering. Except among a comparatively favored few located in large cities, the doctor does not enjoy a large income and his time is never at his disposal, owing to the many calls made upon him throughout the twenty-four hours of the day.

It can hardly be denied that there has been a growing unrest in the profession. State medicine has been talked about, and a certain number of the profession have felt that we have already gone too far toward it. State medicine is a bogey to American physicians and properly so, we believe. Just where to draw the line between State care and care by the family physician has been a puzzle for many years, and many believe that there is too much trespassing upon the field of the private practitioner, or, as a recent writer<sup>1</sup> has put it, "the State is becoming too paternalistic in health matters. . . . The family physician is the most important member of society and upon whom there rests the responsibility for protection of the health of the public more than upon any other factor in public health."

Recently the State Medical Society of Michigan<sup>2</sup> adopted a resolution instructing the President to appoint a committee to study the problems outlined, which they believe require immediate and critical attention. Among the reasons brought forward as producing the present emergency, are mentioned public health service operations, the Medical Corps of the Army and Navy, the Veteran's Bureau, narcotic and child health bureaus, federal and state laws, licensure laws, decisions of the Supreme Court, etc. They recognize without question the right and the duty of the government to impose reasonable requirements upon doctors and medical practice. They list also nineteen activities which have interfered with the doctor and medical practice, including the foundations, some of which are active in promoting county health units, state universities with hospitals and medical service, state tuberculosis sanatoriums, crippled children's work and hospitals, city health and school departments, welfare departments, etc., in addition to medical services conducted by industrial corporations, clinics, private and endowed hospitals, etc.

The problems confronting the medical profession, many of which have been voiced by the Michigan Society, are real and urgent. The current medical journals have recently carried a number of articles on the general subject, the particulars of which are given in the resolution mentioned.

In various states and cities, official commissions have been appointed to study legislation concerning general health, child welfare, tuberculosis, etc. Unofficial health organizations have performed most useful educational service. Many state medical societies have been considering the question of public relations, but coöperation so far has not been brought about to the degree which could be desired. "If we do not take the leadership, government will have to do it because public sentiment, when aroused, is quite likely to find ways of getting what it needs. Medicine is today in a strategic position. It can take leadership in the solution of problems. . . . Its public position on public health questions will determine its future influence. Health organizations get their chief incentive in medicine's failure in meeting present-day health problems."

Medicine has advanced tremendously—so has public opinion. We are going through a stage of transition. The doctor has possibly been too much engrossed in healing the disease and forgetting the patient, as well as the social problems involved in medical practice. The profession has become overspecialized, and the average doctor has been led to feel that some of the specialties—mental hygiene, for example—are beyond the ken of the average man. Certainly it involves knowledge and experience which the average practitioner does not have, and it is hard to see where he is going to obtain either, and at the same time make a living. Other problems, such as those presented by venereal diseases, are pretty well understood by the average practitioner, but involve tremendous legal and social obligations and responsibility. The clergy, and other well meaning but medically ignorant people, object to prophylaxis on moral grounds, apparently forgetting the innocent sufferer. The physician is a health officer, and as a rule, recognizes his duties very much more clearly than the social organizations which have interested themselves in the matter. Many believe with reason that we are in a state of transition which carries with it necessary problems, and some upset. The medical profession has shown the need of all of the services given by lay organizations, including vital statistics, public health engineering, etc. It has failed to recognize the differences between the practice of curative medicine and prevention, and also the fact that public health work constitutes a special calling, and requires special training. If the medical profession

is to serve itself and guard the honorable position which it holds, and has held at least since the Middle Ages, it must still lead in health matters, and be even more ready than in the past to coöperate in public affairs.

## THE TWO-YEAR PERIODICITY OF MEASLES

THE Central Public Health Committee of the London County Council forecasts an epidemic of measles in London during the autumn of 1931 and winter of 1932.<sup>1</sup> Measles in epidemic form occurs in that city at intervals of 2 years, beginning late in the autumn and lasting some 6 or 7 months. Since the last epidemic occurred in 1929-1930, the next is expected about this time. About 50,000 children are affected during each outbreak. This periodicity at 2-year intervals has been observed since 1918 in New York City, though experience leads them to expect high prevalence of the disease in the even-numbered years and low prevalence in the uneven.

The year 1931, however, has been an exception to this rule, and the New York authorities are seeking an explanation. For the first 9 months of this year, 26,238 cases have occurred against 22,865 for 1930.<sup>2</sup> In the *Weekly Bulletin* a table for 12 years is given showing without exception the greater prevalence of the disease in even-numbered years, extreme cases being 2,101 for 1927 against 35,008 for 1928. The reasons for the greater prevalence observed for 1931 over that expected, and over that for the uneven-numbered years, are not clear, and the event has upset the calculations of the health authorities.

In London the 2-year periodicity seems to be very well established, and since the epidemics begin late in the autumn of the uneven-numbered years, we may say that most of the epidemics occur in the year following with the even number, which accords entirely with the observations in New York, though the London practice of combining the autumn and winter in this respect makes the comparison a little uncertain.

In London the deaths from measles have shown very gratifying decrease, from 9,538 in 1906-1910, to 3,715 in 1926-1930, the figures for the intervening years, with one exception, showing a steady decrease.

The plan in London is: (1) To make every effort to avoid contraction of the disease until after the 3d or 5th year, since the younger

the child, the more danger there is of serious illness; (2) To secure adequate nursing and medical care; (3) To remember that measles is particularly fatal among undernourished children and those living in bad surroundings. These causes operate in the same way in this country, though we would add to this particular program the avoidance of tuberculosis, since in both white and colored, but especially in the latter, tuberculous infection leads to a very high mortality following measles.

### SURGEON GENERAL HUGH S. CUMMING REAPPOINTED

THE nomination of Surgeon General Hugh S. Cumming of the U. S. Public Health Service to succeed himself was sent to the Senate on January 26 by the President. This is a cause for congratulation to the country and to the members of the Service. Under his administration, the activities and influence of the Service have constantly increased in various fields of endeavor. The recent establishment of the National Institute of Health has been one of the great advances which have taken place.

General Cumming has been Surgeon General during an exceedingly trying time. It is only necessary to recall the epidemics of meningitis, poliomyelitis, psittacosis, the flood conditions on the one hand, and the drought on the other, all of which have raised problems of extreme importance, affecting large areas of this country, and incidentally our relations with other countries with which modern means of transportation have coupled us so closely. All of these emergencies have been met and handled with judgment and efficiency.

Among the many perplexing complications which engage the attention of the authorities in Washington, it is a relief to turn to the work of the U. S. Public Health Service under General Cumming with its smoothness of operation and the accomplishment of worthwhile results of vast importance to health and happiness of our nation.

## ASSOCIATION NEWS

### DR. PETER H. BRYCE

THE medical profession has learned with deep regret of the death on January 15 of Dr. Peter Henderson Bryce, President of the American Public Health Association in 1900, and a member of its Executive Board from 1916 to 1921.

Distinguished alike as a physician and as a man of letters, Dr. Bryce was a product of Brant County, Ontario, having been born at Mount Pleasant on August 17, 1853. His education was received at Upper Canada College and the University of Toronto, from which institution he was graduated as B.A. in 1876. Progressively he acquired the degrees of M.A. (1877), M.B. (1880) and M.D. (1886).

He practised first in Toronto and Guelph, and was later appointed professor of chemistry at the Agricultural College in the latter city.

An outstanding member of the medical profession in Canada, Dr. Bryce had occupied many important positions. He was founder of the Ontario Department of Health, serving as secretary from 1882 to 1904. He was appointed chief medical officer of the Department of the Interior and Indian Affairs in 1904, a position he occupied until his retirement in 1921.

Since his retirement, he had identified himself with many learned societies. For a number of years he was President of the Arts and Letters Club of Ottawa, of which he was one of the early members and staunch supporters, and he

also became a member of the Canadian Historical Society.

PETER H. BRYCE, M.D.

The author of several works, including scientific volumes, Dr. Bryce had only recently completed the life of Sir Oliver Mowat, which is expected to perpetuate his memory in the field of Canadian letters.

Dr. Bryce joined the A. P. H. A. in 1883, and was made an Honorary Fellow in 1922.

## NEW MEMBERS

*The following list includes applicants who have been approved for membership in the A. P. H. A. by the Sub-committee on Eligibility. These new members have requested affiliation with the sections indicated, and action by the Section Council will follow.*

*Health Officers Section*

- Dr. John E. Burch, Daytona Beach, Fla., Health Officer  
 Avon H. Elliot, M.D., Health Department, Wilmington, N. C., County Health Officer  
 Ernest M. Ewers, M.D., Somerset, Ky., Director, Pulaski County Health Department  
 Lunsford D. Fricks, M.D., 216 Canadian National Pier, Seattle, Wash., Medical Director, District No. 6, U. S. Public Health Service  
 Joseph C. Healy, M.D., 1 Market St., Lockport, N. Y., Health Officer  
 James H. McEachern, M.D., 401 City Hall, Tampa, Fla., City Health Officer  
 Z. V. Moseley, M.D., Kinston, N. C., County Health Officer  
 J. W. Roy Norton, M.D., Rocky Mount, N. C., City Health Superintendent  
 Louis J. Petritz, M.D., City Hall, Venice, Calif., Assistant Health Officer  
 Van A. Stille, M.D., Benton, Ky., Assistant Director, Bureau of County Health Work  
 Dr. James A. Summers, City Hall, N. Little Rock, Ark., City Health Officer  
 Clarence H. White, M.D., Box 480, Henderson, N. C., Health Officer of Vance County  
 W. Carter Williams, M.D., Health Department Building, Franklin, Tenn., Director, Williamson County Health Department  
 Richard F. Yarborough, M.D., Louisburg, N. C., Health Officer of Franklin County

*Laboratory Section*

- Maurice P. Lafleur, M.D., 1112 Route Lafleur-Duchêne, Port-au-Prince, Haiti, Teacher of Hygiene  
 Lyndon R. Rhodes, 67 Quincy Shore Drive, Atlantic, Mass., Dairy Chemist, White Bros.  
 Stanley J. Thomas, Ph.D., Lehigh University, Bethlehem, Pa., Professor of Bacteriology  
 Abdel M. Wahby, D.V.M., Bacteriological Laboratory, Cornell University, Ithaca, N. Y., Research Worker  
 Herbert C. Ward, 6214 3d Ave., Kenosha, Wis., Director, Biological Laboratory, U. S. Standard Products Co.  
 D. Evelyn West, Box 1001, Hartford, Conn., Microbiologist, State Department of Health

*Public Health Engineering Section*

- Louva G. Lenert, State Board of Health,

- Jacksonville, Fla., Chief Engineer; Director, Bureau of Sanitary Engineering  
 Chris G. Lightcap, R. R. 2, Box 63, Phillipsburg, N. J., Sanitary Engineer  
 Marvin T. Rowland, Chamber of Commerce, Texarkana, Tex., District Engineer, State Health Department

*Industrial Hygiene Section*

- Paul A. Davis, M.D., 1436 Delia Ave., Akron, O., Assistant Medical Director and Hygienist, Goodyear Hospital and Factory  
 Max Kummel, M.D., 315 Central Ave., East Newark, N. J., Industrial Physician and Surgeon

*Food and Nutrition Section*

- Harriet I. Albee, 108 Warren St., Concord, N. H., Assistant Chemist and Bacteriologist, State Board of Health  
 Julian H. Toulouse, Ph.D., 726 Bond Building, Washington, D. C., Director of Laboratory, American Bottlers of Carbonated Beverages  
 Mr. William J. Warner, 165 Capitol Ave., Hartford, Conn., Dairy and Food Commissioner

*Child Hygiene Section*

- Jozef Lubczynski, M.D., Grochowska 36, Warsaw, Poland, Health Officer (Assoc.)  
 Dr. Lloyd P. MacHaffie, 162 Clemow Ave., Ottawa, Ont., School Medical Officer  
 Leonard J. Piccoli, Ph.D., 88 E. 208 St., New York, N. Y., Professor and Head of Department of Materia Medica and Physiology, Fordham University

*Public Health Education Section*

- Herbert F. Hirsche, 90 Livingston St., New Haven, Conn., Executive Secretary, Cancer Control Committee, Department of Health  
 Mary A. Hodge, M.D., 319 Gittings Ave., Baltimore, Md., Professor of Physiology and Hygiene, Goucher College  
 J. Alphonse Lapierre, M.D., Ste Anne des Monts, County Gaspe, P. Que., Medical Officer of Health

*Epidemiology Section*

- Anson B. Ingels, 194 Adelaide Ave., Providence, R. I., Epidemiologist, State Public Health Commission

*Public Health Nursing Section*

Mrs. Anna Van W. Castle, 911 Delaware Ave.,  
Wilmington, Del., Director, Visiting Nurse  
Association

Letitia E. Lynch, County Health Dept., Santa  
Barbara, Calif., Supervising Nurse

Emma R. McLeod, 417 George St., New  
Brunswick, N. J., Public Health Nurse, Di-  
rector of Visiting Nurses Association

Alice M. Vallette, Potosi, Mo., Public Health  
Nurse, Washington-Iron Counties

Juanite R. Zamora, R.N., Thermal, Calif.,  
Public Health and School Nurse

*Unaffiliated*

Charles H. Dumais, M.D., 315 rue Lafontaine,  
Riviere-du-Loup, P. Que., Sanitary Unit  
Inspector

H. Wirth Edwards, M.D., Seligman, Mo.  
(Assoc.)

## TRAINING AND PERSONNEL

THE following bill which is before the legislature in the State of Massachusetts will be of news interest to the members of the Association as a development in the field of Personnel.

*House Bill 262*—An Act providing for Examining and Licensing Local Public Health Officers or Agents. 1932.

*Section 1*—On and after 1 year from the date of passage of this act no person shall be appointed as local health officer, or as an executive or agent of the board of health of any town or city having a population of 10,000 or more, or as the executive officer or agent of any group of towns having a combined population of 10,000 or more, unless he has been licensed as a health officer by the State Department of Public Health.

*Section 2*—A license as a health officer shall be issued by the State Department of Public Health to each person who passes an examination in sanitation and public health procedures.

*Section 3*—The examinations shall be conducted in such manner and at such times as the state department of public health shall determine.

*Section 4*—This act shall not prevent any local board of health from continuing in office, without examination and license, any health officer or agent who fills such office at the time of passage of this act.

*Section 5*—A fee of \_\_\_\_\_ shall be paid to the State Department of Public Health by the applicant for each examination taken for a license as health officer.

This bill is presented by the Massa-

chusetts Civic League with the endorsement of the State Department of Public Health, the Massachusetts Association of Boards of Health, the Schools of Public Health in Massachusetts, and with the support of the many professional workers.

In 1927, the American Public Health Association approved the "Principle of the Licensing of Health Officers Upon the Basis of Their Professional Qualifications." The bill quoted above is certainly in accord with this general principle.

No model bill has yet been developed within the Association, but many leaders in public health administration believe that the time has come for legislative action setting standards for appointments to various positions in the public health field. The Committee on Training and Personnel is at work through its sub-committees in the development of a vigorous program for developing both public support and legislative action looking toward the improvement of tenure for workers now in public health positions and toward the selection of trained individuals for future appointments. Subsequent issues of the JOURNAL will carry reports upon committee activities.

# PUBLIC HEALTH ADMINISTRATION

## VISUAL RATE CHART

GEORGE B. DARLING, JR., DR. P. H.

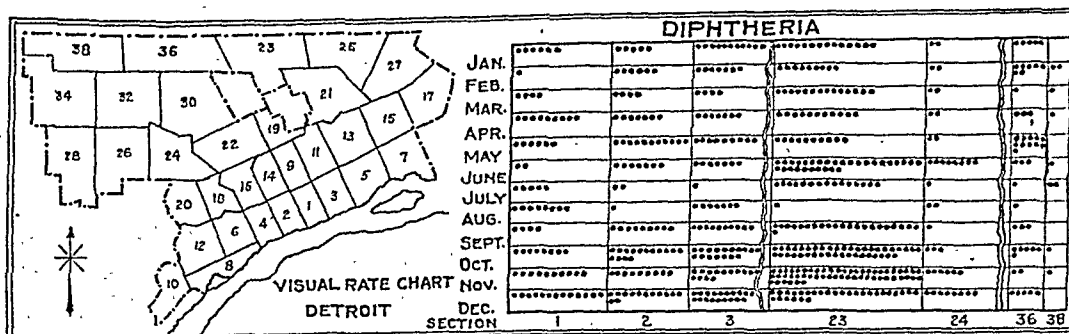

*Assistant Epidemiologist, Department of Health, Detroit, Mich.*

AN epidemiological master chart useful in the graphic presentation of epidemiological data by districts was submitted in a recent article in this section.<sup>1</sup> Although primarily intended for annual rates this chart may readily be adapted for routine or running records. In watching the situation from day to day or from week to week the usual procedure is, of course, to use spot maps showing approximately the location of the case, death, or service. This method has considerable practical merit, but it is very difficult to combine with the spot map graphical information concerning density and character of population, and obviously it is impossible to derive even relative ratios. Many methods have been proposed to get around these difficulties.

The visual rate chart presented herewith (only a fragment of the entire chart is presented in the accompanying illustration) has a certain usefulness in this regard. It may be used in connection with a spot map showing the exact location of the case, or it may be used alone if the general location need not

be known closer than the sanitary district. A detailed account of the construction of the chart was presented in the previous article. For practical purposes the idea is essentially that a bar is divided into sections according to the proportion of the population of the various districts. For instance, the width of section one is in the same proportion to the total length of the bar as the population of the section is to the total population. It may be desirable to divide the bar further into time elements. In the illustration months are used for this purpose.

When cases occur, instead of being spotted in the area on the geographical map to which they belong, they are spotted in the appropriate section of the bar chart. The dots and the spaces between need not be exactly of the same size but should be reasonably so. By referring to the illustration it will be seen that it is possible to put 13 dots along the horizontal axis of section 1 while only 5 dots of approximately the same size can be put in section 36. If there are 13 in section 1, and 5 in sec-

tion 36, the rate for the two districts must necessarily be the same (see the month of December). If there are only 6 dots in section 1, with 5 dots in section 36, it is apparent that the rate in section 36 is twice that in section 1 (see January). Again, if the line of dots goes twice across the available space in 36 and only half way in section 1, the ratio is obviously 4 to 1 (see May). It is thus apparent that comparable visual rates are available at any time since the number of cases will be shown in direct proportion to the population exposed.

Such a chart has a definite place in current statistical tabulations where it is important to know not only the number of cases but relative attack rates by

districts. Correlation of this information with that provided by the epidemiological master chart is useful in a rapid appreciation of the factors involved in the progress of an epidemic.

Dependent upon the use to which the data are to be put, the chart may be kept by convenient time intervals or may be made cumulative. The principle is essentially the same.

The visual rate chart has proved to be of considerably greater value than the ordinary spot map in that it permits the instantaneous derivation of visual rates without additional laborious book-keeping and statistical analysis.

#### REFERENCE

1. Darling, George B. Epidemiological Master Chart, *A. J. P. H.*, 21, 6: 665 (June), 1931.

**New York Health Center Districts Statistical Reference Handbook**—The Committee on Neighborhood Health Development of New York City, of which the Commissioner of Health is chairman, has issued a handbook of statistical reference data which is of value to public health and public welfare administrators as well as to statisticians. The 1930 federal census figures are given for each of 30 health center districts together with population trends covering the past 10 years. Information is presented for each district concerning births, deaths from all causes, infant deaths, tuberculosis deaths, registration of new cases of pulmonary tuberculosis, venereal diseases, and other communicable disease reports, with corresponding rates. School registration has been brought up to date. A section also deals with public health nursing requirements.

The report is designed to furnish a background for the further and more detailed study of health needs in each community as a basis for the sound and orderly development of district programs of public health, and should be an indispensable background

to district health officers for the future evaluation of local programs. It is also hoped that the handbook will be useful to the voluntary agencies in helping them to adjust their programs to local needs, and that it may prove of interest to other communities wherever the problem of district health center development is being considered.

It is noteworthy that the Committee on Neighborhood Health Development, which is aiding the Department of Health in the planning of district health centers, has in its membership two representatives from each of the five county medical societies.

The complexity, as well as the diversity, of the problems of the various districts in the city becomes apparent when the data presented are studied. Density of population in the city varies from a little less than 3,000 per square mile to slightly less than 85,000 per square mile. On the average, there are 125,000 cases of communicable diseases reported in an average year in greater New York. In normal years for 15 of the common communicable diseases, the case rates vary in different areas from 895 to 2,550 per 100,000 population.

The general death rate for the city as a whole was 10.7 in the 2-year period 1929-1930. The rate for Manhattan was 13.6; for the Bronx 8.6; for Brooklyn 10.2; and for Queens 8.9. Similarly, for the same period, infant mortality varied. The rate for the city as a whole was 57; for Manhattan 74; for the Bronx 47; for Brooklyn 55; and for Queens 49. But there was even greater diversity in infant mortality in the various health districts, the highest rates occurring in Central Harlem. The statistical data and excellent maps included in this handbook render it an indispensable aid in program planning.

New Haven, Conn.—In this city of 162,658 population, there were 14 cases of diphtheria, with 1 death, an adult, in 1930. There were no cases in the age group under 5 years. Five of the total cases were in institutions, 4 being in an orphan home. One of these cases was a new boy, 2 others had received 3 toxin-antitoxin administrations the previous year, while 1 boy had given a negative Schick reaction on 3 tests. The fifth case in an institution, a nurse, had received 3 inoculations the previous year. During the year there were found 214 carriers, 47 of these being in the age group under 5, and 8 being in the age group over 15. All but 5 were nasal carriers, and only 11 resulted in

positive virulence tests. Eighty per cent of the carriers were found by the communicable disease bureau personnel, 15 of the cases occurring among new arrivals seeking school admission.

During the year there were 200 cases of measles with no fatalities. For 4 years it has been the practice of the health department to provide special medical care of cases of measles and whooping cough in their homes if no private physician is in attendance. Relatively few measles cases were hospitalized in this epidemic, and the results of the supervision are noteworthy.

Among the 93 tuberculosis deaths, 69.8 per cent occurred in hospitals or sanatoriums and 78.5 per cent had been hospitalized. Eight-one of the cases were known to the bureau before death. A tuberculosis death rate of 57.2 is recorded. There were 341 new cases reported during the year, 278 having been reported by physicians. Of the 18,811 home visits made by the Visiting Nurse Association, 9,108 were to diagnosed cases, while 2,543 visits were made to post-sanatorium cases. The 349 cases admitted to hospitals and sanatoriums during the year received a total of 69,717 days of care.

At the summer camp, 101 children stayed an average of 65.5 days.—*Annual Report*, New Haven Dept. of Health, 1930.

# LABORATORY

## INTRADERMAL METHOD OF VIRULENCE TESTING OF *CORYNEBACTERIUM DIPHTHERIAE* \*

J. RALPH WELLS

*Department of Bacteriology and Immunology, Washington University School of  
Medicine, Saint Louis, Mo.*

THE procedure of determining the virulence of *Corynebacterium diphtheriae* by means of intradermal injection of pure cultures, as modified by Zingher and Soletsky<sup>1</sup> from Neisser's<sup>2</sup> method, or of mixed cultures as advocated by Havens and Powell,<sup>3</sup> Force and Beattie,<sup>4</sup> and others, has found considerable practical use because of its apparent accuracy, combined with its relative economy and simplicity. It has been adopted as a routine in some laboratories, while in others its use has been limited mainly to epidemiological investigations involving cases or carriers of diphtheria. It is also valuable in the testing of numbers of stock strains of these organisms when knowledge of their toxigenicity is requisite to other studies involving this group of organisms, since it is possible to test satisfactorily from 8 to 12 strains or more on one guinea pig, or 20 to 30 cultures on a large white rabbit, the latter animal being considered by some workers<sup>5</sup> as more sensitive to diphtheria toxin.

In attempting to utilize this method of testing virulence of diphtheria-like organisms, the author has recently observed a complication which seems sufficiently important to be reported, as there appears to be no discussion of it in periodicals commonly available in the English language. It is a point involving the interpretation of the results of intradermal tests of recently isolated cultures of *C. diphtheriae* and is inherent in the principle upon which this method is founded, viz., tissue injury due pre-

sumably to the toxigenicity of these organisms.

While testing a number of recently isolated pure cultures incident to another study in progress, using 0.1 c.c. amounts of 24 hour broth cultures of 8 different strains on each of two guinea pigs (Nos. 332 and 333) one of which (No. 332) had been protected 2 hours previously by intraperitoneal injection of 400 units of diphtheria antitoxin, it was noted that the corresponding sites of inoculation of one culture (No. 1177a) developed on both guinea pigs a severe necrosis by the end of the first day. These lesions increased in size from about 1 cm. diameter to approximately 1.5 cm. by the second day, while all sites of injection of other cultures remained distinctly negative on the protected animal and just as clearly positive on the unprotected guinea pig which died sometime during the 2d night after the inoculations were administered. Sloughing of the superficial portion of the skin occurred on pig 332 between the 3d and 4th days.

In common practice, especially when dealing with "field-cultures," such reactions occurring on both the test and the protected animals are likely to be read as negative. Thus Zingher and Soletsky,<sup>1</sup> who originated the idea of using one test guinea pig and one protected guinea pig in this type of virulence testing, say:

The results of the tests are noted in 24, 48 and 72 hours. Virulent strains produce a definitely circumscribed, local inflammatory lesion,

which shows a superficial necrosis in from 48 to 72 hours. In the control pig the skin remains normal, if the injections have been accurately carried out.

Havens and Powell,<sup>3</sup> who are the first to report the use of this method with "original diagnostic cultures," state that "there is but one dependable criterion for virulence, viz.; necrosis of the superficial layers of the skin of the test pig, while it is absent in the control."

Bull and McKee<sup>4</sup> discussing their work with "whole-cultures" emphasize that "the absence of necrosis in the control animal was considered to be an indispensable prerequisite to a positive reading." Eagleton and Baxter<sup>5</sup> reporting their modification of Zingher and Soletsky's method<sup>1</sup> in England say:

Readings are taken for the next 3 days. In the case of a virulent diphtheria bacillus the control animal shows nothing or a faint transient flush; the other animal shows a definite rose-red swelling which becomes more marked at each successive reading, and may terminate in slight necrosis.

Moreover, Force and Beattie,<sup>4</sup> who reported the use of intradermal tests for virulence of these organisms in "field-cultures" only a few months after Havens and Powell,<sup>3</sup> specifically state that "any lesions where sloughing occurs on both animals are not produced by diphtheria toxin." The lesion on the protected animal would usually be explained as due either to the presence of contaminating organisms, to allergy of some sort, or to faulty technic.

However, the cultures used in the tests being reported here had been plated and single, well isolated colonies picked to Loeffler's slants, and, in so far as morphology and cultural characteristics are concerned, appeared to be typical of *C. diphtheriae*.

The protected animal (No. 332) was kept under observation until its death on the 25th day after the tests were begun. It appeared to be in good health for 8 to 10 days at which time it ap-

peared sick, began to lose weight and later developed partial paralysis, and at the time of death weighed only 252 gm. as compared to its original weight of 487 gm.

All these conditions suggested that we were dealing with a phenomenon similar to that reported by Feierabend and Schubert<sup>7</sup> and Ivanić, Dimitrijević-Speth and Jovanović<sup>8</sup> and seemed to warrant further inquiry, because of the importance of missing the recognition of a very virulent strain of diphtheria organisms by calling such a reaction negative in routine work. Consequently the culture (No. 1177a) producing positive reactions on both test and control guinea pigs was replated but no contaminating organisms were found. From these plates four well isolated colonies were selected, and transferred to Loeffler's slants and to broth and incubated 24 hours.

At the same time another culture (strain No. 377) which had shown itself toxic in the first test without producing any evidence of reaction in the protected pig was grown in broth to be used with the above cultures in subsequent tests as a control. The morphology and fermentative behavior of these cultures were found to be the same as before.

With these 6 cultures the test was repeated with the result that all sub-cultures of No. 1177a again gave definite, although somewhat smaller, necrotic areas on both protected and control guinea pigs in 24 to 30 hours. The lesions increased in size to 0.5 cm. or more in diameter by the 2d day on both animals, while culture No. 377 gave a typical strong inflammatory reaction, with necrosis on the unprotected pig and none on the control. The test guinea pig died in about 48 hours, while the protected animal appeared to be still in good health at the end of 18 days. The lesions at the sites of injections on this animal persisted with-

out evidence of subsiding until about the 7th or 8th day. At the end of 16 days they are still clearly evident but appear to be healing rapidly, the animal showing no general ill effects.

According to the work of Feierabend and Schubert<sup>7</sup> the evident differences in intensity and outcome of the reactions in the first and second tests is to be explained on the basis of attenuation from growth on artificial mediums, as these workers and others<sup>8</sup> found that such organisms rapidly decrease in virulence when grown upon culture mediums.

The occurrence and persistence of lesions at the sites of injections in protected animals are explained by these investigators as due to the fact that there exists among the many strains of diphtheria bacilli some which, in addition to the power to produce a necrotizing toxin, possess a high degree of "invasiveness."

The work of both these groups of investigators would indicate that the latter properly accounts for the persistence of the organisms in the tissues at the sites of inoculation even in spite of the presence of antitoxin which is administered previously. They found that 200 units would not save the lives of guinea pigs receiving intradermal inoculation with strains of this character, and at autopsy the bacilli could be recovered from various internal organs, as well as from the nasal discharges. They believe that the protected animals in such cases die from the effects of toxin produced at these various focuses by bacilli which have invaded the tissues and survived the period of passive protection afforded by 200 units of antitoxin. They report the prevention of such an invasion and its consequent

fatal termination by the administration of an antibacterial serum, while the fatal result of such an infection was obviated by the use of 1,000 units of antitoxin.

Fermentation tests in Hiss serum water with filtered sugars, and phenol red as an indicator, were made previous to the virulence tests and all strains gave acid production in dextrose, maltose, dextrin, and galactose in 7 days, but not in lactose, sucrose and mannitol. However, strain No. 1177a and some of the others showed a slight but distinct change of the phenol red (from approximately pH 7.8 to pH 7.2) in saccharose in 24 and 48 hours which then reverted to alkaline and remained so.

These circumstances appear to warrant emphasizing the necessity for studying more carefully all intradermal virulence tests of suspected diphtheria cultures showing local reactions on both protected and unprotected pigs, before calling them negative, and attempting to explain them on some other premise. This would seem to be especially true in routine work involving "whole"- or "field-cultures," and in cases where subcutaneous virulence tests lead to death of both animals.

## VITAL STATISTICS

Smallpox from 1929 to 1931—The rough total figures for smallpox cases and deaths reported in the various continents show that in Africa, America, and Asia an increase took place from 1929 to 1930, while a marked fall occurred in 1931, the incidence during the first 6 months of this year being less than half of what it was during the corresponding period of 1930. In Europe, the situation has remained practically unchanged from 1929 to 1931.

The progress that has been made toward the eradication of smallpox since 1920, when nearly 200,000 cases were reported in the European countries and a few countries outside of Europe, is shown by comparative figures for this decade. In the 10 years, the number of cases was reduced to less than 16,000, of which 11,839 occurred in England and Wales alone. Most progress was made in the Union of Soviet Socialist Republics where vaccination was generalized after the revolution, and in Poland and Roumania. Considerable improvement took place also in Germany, where the number of cases reported fell gradually from 2,042 in 1920 to 2 in 1930; and in Italy, where the corresponding figures are 26,453 and 2. In Austria, Belgium, Bulgaria, Denmark, Estonia, Latvia, and Norway, no cases were reported in either 1929 or 1930, while one or two cases only occurred in Germany, Finland, Italy, the Netherlands, Sweden, and Switzerland during 1930. In the Netherlands, where smallpox is, as a rule, very rare, an outbreak of 703 cases imported into Rotterdam occurred in 1929. Vaccinations of the citizens reduced the incidence to 84 cases during the last 3 months of the year. Only 20 deaths

were noted throughout the period and no new case was reported after January 1930. The incidence of smallpox varies in France, from 1 to several hundreds, largely among foreign or colonial laborers.

In England and Wales, variola minor has increased more or less continuously since the end of the war (from 280 cases in 1920 to 14,767 in 1927, 10,968 in 1929 and 11,839 in 1930). The fatality rate is exceedingly small: 0.24 per cent in 1930. The geographical distribution of the disease has changed markedly in the last 4 years. Generally speaking, smallpox incidence has declined in northern England (Yorkshire) and has increased in the south and southeast, as well as in London. In 1929, a marked rise took place in its prevalence in London (1,903 cases against 296) and in Northampton, while a fall was observed in Glamorganshire and Monmouthshire. The 1930 Annual Report of the Chief Medical Officer of the Ministry of Health shows that, out of 3,518 patients under 15 years of age, 3,509 (99.8 per cent) were unvaccinated; from ages 15 to 40, out of 3,231 cases, 2,919 (90 per cent) were unvaccinated; and above the age of 40, out of 1,100 cases, only 262 (23.8 per cent) were unvaccinated. In Scotland, where smallpox had declined to a low level from 1922 to 1926, an abrupt rise occurred in 1927, more than 1,500 cases being reported that year and more than 1,400 the following year. A great improvement took place in 1929, when only 18 cases were reported, and in 1930, with 11 cases.

In Northern Africa smallpox is declining (Morocco, Algeria, Tunis) as vaccination progresses, the most remark-

able success being achieved in Egypt. In the latter country, smallpox claimed 2,677 cases with 544 deaths in 1926; in 1930, it caused only 14 cases without deaths. This is undoubtedly due to the vaccination campaign, begun at the end of 1925 and completed in 1926. Approximately 14,600,000 vaccinations were performed, thus reaching practically the whole population, except that in Cairo and Alexandria, where only 619,637 persons were vaccinated in 1930. In Central and Eastern Africa, the prevalence of smallpox, which has been increasing in recent years, continued its upward movement in 1929 and 1930. The observations made in Northern Rhodesia in 1928 are of particular interest. Apparently severe smallpox, alastrim (or amaas) and chicken pox, prevailed at the same time. Its low level in many instances resulted in the spread of the disease (4,035 cases in 1928, 3,855 in 1929 and 4,078 in 1930). In 1929, the smallpox fatality rate was 9.5 per cent—while the rate for alastrim was 7.8—a very small difference. From these indications it was concluded that for administrative purposes no distinction should be made between alastrim, amaas Kaffir-pox, and that every case should be treated as smallpox. The failure of vaccination to control the epidemic was due to inactive vaccine. In some districts, the lymph was inert through exposure to tropical heat, in others it did not give more than 30 per cent of "takes."

Apart from China, for the interior of which no statistical data are available, British India constitutes the most important focus of smallpox in Asia (more than 90 per cent of the cases reported). In 1929, the number of cases reported in India was slightly less than 150,000, and rose in 1930 to 215,204, the latter figure representing roughly the mean incidence of the disease for the three years 1926, 1927 and 1928. The numbers of deaths so far known for 1929

and 1930 are 34,393 and 48,860, but these figures are far from complete. When, after two or three years, revised mortality statistics are available, the provisional figures are more than doubled. Thus, the provisional figure for 1927, 51,776, became 118,197 when revised, and the 39,981 deaths in 1928 grew to 96,123. The high fatality rate of smallpox in India (above 50 per cent) shows clearly that variola major is prevalent there. In sharp contrast with the high prevalence of smallpox in India is its low incidence in Ceylon, where, in recent years, it has seldom attained 1 per 100,000. In Siam and Malaya the incidence of smallpox is comparatively low; and remarkably low in Java and in the Philippines. In the whole of French Indo-China, only 995 cases were reported during the first half of 1931, as against 3,502 during the corresponding period of 1930, but the fatality of the disease remained high (between 30 and 40 per cent). In Japan, the number of smallpox cases is practically negligible, while in Chosen it amounts to a few hundred every year and seems to be increasing. Throughout the Far East, it is the severe type of smallpox which is encountered.

In the Near East, the smallpox situation is, on the whole, favorable. The disease is practically non-existent in Palestine and Transjordan. It is disappearing in Syria; in Turkey a total of 561 cases was reported in 1929, 836 in 1930. The fatality rate varied from one local outbreak to another, ranging from 10 to 50 per cent, but averaging from 15 to 25 per cent. As in past years, New Zealand was free from smallpox in 1929 and 1930. Australia was also free but for 4 imported cases and 1 contact infected by them.

In Northern America the prevalence of a mild type of smallpox remains high. It has increased slowly during the last 5 years. In the United States, 42,282 cases were reported in 1929 and 46,712

in 1930. On the other hand, the fatality rate of the disease, which was already low, has declined still further from 1.8 per cent in 1925 to 0.4 per cent in 1929. In Canada, it was 0.4 per cent in 1929 and in 1930 there were no deaths at all. In both countries, an improvement occurred in 1931, the number of cases notified during the first half of the year being considerably lower than during the corresponding period of 1930—520 against 1,033 in Canada; 24,465 against 38,921 in the United States.

In the western and Rocky Mountain States smallpox is much more prevalent than in those east of the Mississippi. The highest incidence prevailed in South Dakota. Some New England States enjoy freedom from smallpox; such is also the case for Texas, where this freedom is quite remarkable because of the high prevalence of the disease in the adjacent states of Coahuila and Chihuahua, across the Mexican border where mortality rates of 61 and 48 per 100,000 respectively prevail. An idea of the prevalence of smallpox in Mexico may be derived from the number of deaths reported even though notification of cases for the whole of the country is lacking. These deaths numbered 5,497 in 1929 and 9,208 in 1930 (56.1 per 100,000), while the figures for the first months of 1931 show a further increase. There is no doubt that virulent smallpox constitutes a serious public health problem in Mexico.—League of Nations, *Month. Epidemiol. Rep.*, Oct. 15, 1931, pp. 385–396.

**Health Conditions in American Samoa**—The census of American Samoa, completed in March, 1930, gives an actual population of 9,768 persons, the majority of whom were full-blooded Samoans; the percentage of white persons in the population was so small as to be almost negligible. In 1930 there were 394 births and 177 deaths, result-

ing in a natural increase of 217, bringing the population to 9,985, the figure on which birth and death rates are computed. Based on this figure the birth rate in 1930 was 39.45 per 1,000 and the death rate 17.73, which rate is 3.66 per 1,000 lower than that for 1929.

The present system of collecting vital statistics in American Samoa is such as to make it unlikely that any births or deaths are not reported. This system became reliably operative May 1, 1928. A triple check is made on all births and deaths in the country. The pulenuu of each village as well as the district nurses are required to submit birth and death reports, and these in turn are forwarded to the central public health office where they are again checked for errors. It has become necessary during the year to send several village pulenuu before the secretary of native affairs for failure to report births and deaths. By taking this disciplinary action, the importance of these returns has impressed itself upon the village chiefs so effectively that omission of a birth or death report is practically impossible.

There were, in 1930, 41 infant deaths, giving an infant mortality rate for American Samoa of 104.07 per 1,000 live births. In 1929 there were 48 infant deaths, 7 more than in 1930. Of the 1930 deaths, slightly over half were due to pneumonia all forms (11 deaths) and acute infectious enterocolitis (11 deaths).

An analysis of the 177 deaths in American Samoa in 1930 shows that 47 per cent were due to the combined causes, tuberculosis, pneumonia, and influenza. Tuberculosis in its various forms caused 35 deaths, giving a death rate of 350 per 100,000. The death rate for the year 1929 was 422, which shows that the reduction for the year 1930 was appreciable. Tuberculosis has been the leading cause of death for several years, but pneumonia, with 40

deaths, led the list of causes this year, with a death rate of 400. Filariasis, which was the primary cause of 19 deaths (190 per 100,000), was the 3d most important cause of death.

An interesting departure from the death rates attributed to these causes in most countries is the record of no suicides, the low rate of 20.0 per 100,000 population, for cancer; and the rate of 120.0 for the entire group of diseases of the circulatory system.

No case of smallpox has occurred in this country in recent years—a record which is attributable, perhaps entirely and certainly in part, to a compulsory vaccination law, which is really effective. It is the practice to vaccinate children in all of the schools every year, one or more good scars in a child being considered evidence of immunity. During the calendar year 1930 there were 613 persons vaccinated. Acute infectious conjunctivitis was prevalent during the year, though there was a noticeable reduction, in the number of cases reported, from 3,361 in 1929 to 1,413 in 1930. Owing largely to the frequency of this disease, the percentage of blindness in the population is high, as shown by the Health Department Survey completed on April 1, 1930, which showed that 2.92 per cent of the total population are blind in one eye, and 1.07 totally blind. No cases of whooping cough, measles, diphtheria, or scarlet fever were reported in American Samoa during 1930; there were only 5 cases and no deaths from typhoid fever. Tuberculosis and acute infectious conjunctivitis are two of the primary health problems of the country, and these problems are receiving the concerted attention of health authorities.—*U. S. Nav. M. Bull.*, 30: 104–33 (Jan.), 1932.

**Suicide Statistics**—Part 1 (Medical) of the Registrar-General's Statistical Review of England and Wales for the year 1930 contains a table of

suicide statistics classified by age, sex and method. There were 5,056 suicides in the year, 3,527 among males and 1,529 among females. Four hundred of the male suicides were among men between the ages of 25 and 35, 548 between 35 and 45, 861 between 45 and 55, 869 between 55 and 65, 482 between 65 and 75, and 147 among men of 75 years and upward.

The figures for women do not follow quite the same progression. There were 250 female suicides among women between 25 and 35 years of age, 276 between 35 and 45, 383 between 45 and 55, 289 between 55 and 65, 167 between 65 and 75, and 37 among women from the age of 75 and upward.

The 1930 totals require, of course, to be coördinated with those of previous years and to be adjusted with statistics of the number of men and women of those decennial age groups. As they stand, the figures indicate that both men and women pass through a bad time between the ages of 45 and 55; in the following 10-year period men seem to be less resilient than women.

As to the method adopted, the figures for both sexes combined show 1,348 cases of coal-gas poisoning, 887 of drowning, 753 of hanging or strangulation, 613 of death by the use of cutting or piercing instruments, 262 of death by firearms, and 214 of railway suicides. In proportion to the other sex, more men than women hanged themselves, and more women than men resorted to gas poisoning. Only 8 women committed suicide with firearms, as against 254 men.

Cases of suicide by taking solid or liquid poisons or corrosive substances amounted to 715. Here the availability of the means is reflected by the detailed figures. Lysol—available, as recent litigation has shown, by purchase from automatic machines—was the means of 354 suicides among men and women, while opium, laudanum, and morphia

were the means used for only 5. The latter figure illustrates one valuable result of the restrictions imposed by the Dangerous Drugs Acts and Regulations.

Other means of suicide in this category were carbolic acid (56 cases), hydrochloric acid (53), potassium cyanide (43), prussic acid, hydrocyanic acid (29), oxalic acid (26), ammonia (19), and strychnine (4). Although there were very few "weed killer" cases of suicide, the figures in this category of poisonings may cause the public to consider how far it is desirable to permit the almost indiscriminate retailing of poisons by persons not specially trained in knowledge of the properties of the drugs they sell.—*Lancet*, 221: 1309 (Dec. 12), 1931.

**The Number of Infirm Persons in Germany**—The results of the census of infirm persons in Germany, taken in the year 1925–1926, were published recently. According to a report of these findings, the total number of blind persons in Germany at that time was 33,192 or 5.3 per 10,000 of population. The incidence of blindness among males was much higher than among females, partially because of the large number of men blinded during the war; but even after the deduction of the 2,307 war blind, the incidence among the males was still somewhat higher than among females, as has been the case in former statistical reports. Since the census of 1900, the number of blind persons has increased considerably.

The number of deaf-mutes was 31,-

670, showing a rate of 6 males and 5.1 females per 10,000 of population. In about half, the impairment was congenital. Of the deaf-mutes ages 7 to 20, 88 per cent had received instruction in institutions for the care of deaf-mutes; of those aged 20 to 40, 82 per cent had had such instruction, and of those above age 40, 64 per cent. Of the deaf-mutes above age 20, 82.2 per cent of the men were gainfully employed, mostly as tailors, shoemakers and cabinet makers; of the women, 36.5 per cent were employed chiefly as seamstresses. Of deaf persons who could not hear spoken words even with the aid of an ear trumpet, 8,755 were enumerated, 814 of whom were war injured. Their number was higher in the older age groups; 45 per cent were still gainfully employed: 66.4 per cent of the men and 21.5 per cent of the women. The number of persons with serious bodily infirmities was 276,467; 190,495 men, or 86.4 per 10,000 of population, and 85,972 women, or 29 per 10,000. Even after deducting the 82,972 war injured, the men were still in the majority, chiefly because of the hazards of industry, in the wider sense. The number of persons with slight bodily infirmities was 116,974; 89,784 males (among which were 45,007 war injured) and 27,190 females. The number of persons with mental impairment was 207,514; 105,374 men, including 6,090 war injured, or 37.9 per 10,000 of population, and 102,140 women, or 34.4 per 10,000.—*J. A. M. A.*, 98: 156 (Jan. 9), 1932.

# PUBLIC HEALTH ENGINEERING

## SURVEY OF CONNECTICUT'S SHORE BATHING WATERS\*

WARREN J. SCOTT

*Hartford, Conn.*

THE Connecticut State Department of Health has recently completed a fairly exhaustive survey of the sanitary condition of all of Connecticut's shore waters on Long Island Sound. For many years, and particularly in recent years, the department has received numerous inquiries as to the safety of sections of the shore for bathing. It has been impossible to give intelligent answers to these questions because of (1) the absence of complete data as to sewer outlets along the shore and (2) a dearth of information as to the bacteriological quality of Connecticut shore waters.

The survey was undertaken with the object of compiling sufficient information to enable the department to serve better the citizens of the state in their desire for specific information as to the sanitary condition of bathing areas and also to point out to municipal authorities and other interested persons the "danger spots" along the shore which are seriously affected by sewage pollution.

### POLLUTED BATHING WATERS

It is very difficult to obtain accurate epidemiological evidence as to just what sickness is caused by bathing in polluted

water. An exhaustive survey by the Committee on Bathing Places of the American Public Health Association was confined mostly to indoor swimming pools. The data obtained were not very conclusive. They report an epidemic of typhoid fever at a boys' camp from bathing in polluted water and many cases of eye, ear, nose and throat infections. Some of these latter infections might be due principally to lowering of resistance from chills.

Considerable interest has been evidenced of late by many public health workers in the possibilities of skin infections from bathing. Some minor outbreaks of skin disease among salt water bathers have come to the attention of this department. Unfortunately it is a fact that little is known as to the exact manner of spread of these skin infections—whether the infection has been spread on land rather than in the water or whether the water has acted as a vehicle of transmission from one bather to another, or whether the source of infection has been sewage present in the water.

### METHOD OF THE SURVEY

Maps of the Connecticut shore were prepared to indicate the locations of sewer outlets along the entire Long Island shore. All major outlets were included in the survey although all individual house outlets may not have been spotted. Data were obtained as

\* Adapted from Connecticut Health Bulletin, Vol. 45, No. 12.

This is a contribution of the Committee on Bathing Places of the Public Health Engineering Section of the A. P. H. A.

to the population contributing sewage and other pertinent facts about the sewers. Local health officers coöperated in furnishing considerable information along this line.

Nine hundred and twenty-two sampling stations were chosen at intervals of approximately 1,000 feet along the entire Long Island shore in Connecticut, including areas used for bathing and intervening areas.

Four samples for bacteriological analysis were collected at each station to represent conditions at 4 different stages of tide. The samples were taken as nearly as possible at high, low, one-half ebb, and one-half flood tides. The samples were taken in almost every case from a boat in from 2 to 6 feet of water. They were obtained by dipping a sterilized bottle just below the water surface.

Samples were examined only for the presence of organisms of the coli-aerogenes group. The lactose broth method was employed, using 4 dilutions of the sample for the most part, with the use of 5 dilutions where any serious pollution was suspected. Dilutions were in geometric progression from 10 c.c. to .01 or .001 c.c. Partial confirmation on Endo agar was the limit to which the tests were carried.

#### EFFECT OF WIND

Although records were made of the direction of the wind, no attempt was made to collect samples under different conditions of wind. It is believed that the run of tides is the principal factor to be taken into account in the travel of pollution along the Connecticut shore but minor discrepancies would undoubtedly exist with certain conditions of wind. Of course, too, the tidal movements are frequently influenced by strong winds. In the survey classification described later, nearness of polluting influences and possibilities of shifting direction of pollution travel with different wind conditions were taken into account.

#### EFFECT OF BATHERS UPON BACTERIAL POLLUTION

In attempting to evaluate the analytical results obtained in the course of the Connecticut survey, one of the uncertain factors was believed to be the possible effect on the results caused by bathers in the water at the time of collection of samples. Incidentally, notes were made as to the relative amounts of bathing where samples were collected along beach areas during the survey. It is an unfortunate circumstance in Connecticut that most of our densely populated bathing waters are conveniently located outside of the harbors of our large cities and so are subject to effects of distant sewage pollution. This introduces complications in interpreting analytical studies as to effects of dense bathing.

In 1930, some studies were made at Hammonasset Beach where samples were collected in the midst of some large week-end crowds, and in 1931, similar studies were made at Sound View with crowded bathing conditions. Both areas were chosen because of their relative freedom from any serious outside polluting influences. Bacterial results on the waters sampled with dense bathing were compared with the same waters after tidal changes and with little or no bathing.

While there was found to be a slight increase in the bacterial pollution with dense bathing, the difference was not very significant and there seemed to be little correlation between the quantity of bacterial pollution and the number of bathers. As a result of our studies, we do not believe that the pollution introduced by bathers seriously affects our classification of bacterial results although in some of the country's large, thickly populated bathing areas, different conclusions would undoubtedly be reached. Bacterial pollution by bathers is evidenced by studies of small swimming pools but along the shore the

diluting influences are great and tend to minimize the effect of pollution of the shore waters by bathers.

#### COMPUTATIONS OF BACTERIAL POLLUTION

The values for *B. Coli* content were computed by assuming 1 *B. Coli* originally present in the greatest dilution to give a positive test. For example, positive in 10 c.c. and 1 c.c. and negative in 0.1 and 0.01 c.c. is called 100 *B. Coli* per 100 c.c. If it is desired to express the results as the so-called most probable number of *B. Coli* per 100 c.c., the above figure must be multiplied by the factor 2.3. This would be approximately correct except where so-called anomalous results are obtained, such as a sample showing positive in 10 c.c., negative in 1 c.c., and positive in 0.1 c.c. There were comparatively few such cases and these were treated by recessing to the next less dilution, similar to the process used in scoring oysters. The method used has the advantage of simplicity and furnishes a satisfactory method for comparing results.

The final result for each station was obtained by averaging the 4 computed *B. Coli* counts which seemed as satisfactory as any method. It is realized that undue weight is given in this method to 1 poor result but on the other hand, it emphasizes the occurrence of chance pollution which may be dangerous.

#### BACTERIAL STANDARDS FOR BATHING WATERS

The classification of the safety of bathing waters on the basis of analytical results is complicated by the fact that no accepted standards exist as a basis for such classification. In public health work we have gradually come to adopt certain standards, usually proposed by certain leading scientists and perhaps later changed as a result of experience until these standards are found to be

possible to meet and to be sufficiently stringent to avoid trouble as shown by epidemiological evidence. Our standards for drinking water supplies and milk have been developed in this way. Similarly, bacterial standards for swimming pool waters subject to continuous or intermittent disinfection have been worked out.

In considering drinking water and indoor swimming pools as compared to salt water beaches and large inland streams, there is the difference that ready methods of chlorination or filtration are available in the former case whereas we are dependent on dilution and natural purification in the latter case. There is another distinction which should be borne in mind between the presence of *B. Coli* in salt water beaches or inland streams and in indoor swimming pools. The source of water supply for an indoor swimming pool is either a public water supply or a private water supply relatively free from *B. Coli*. Therefore, *B. Coli* found in indoor swimming pools must be regarded as of human origin. *B. Coli* in the waters of inland streams may be of animal origin and of no great sanitary significance. The same may be true to a lesser extent of harbors receiving a large flow of fresh water from land subject to contamination from animal sources—cultivated land, manure piles, etc.

#### BACTERIAL CLASSIFICATION

It has already been stated that no acceptable analytical classification of bathing waters has ever been made, nor is any arbitrary set of standards entirely satisfactory. It was originally attempted in these studies to set up tentative analytical classifications such as Good, Fair, Doubtful, Poor, and Very Poor. This was later abandoned because of the belief that the classifications were on too arbitrary a basis and because of the possibilities of misinterpretation of results. Instead, a relative

classification of results was attempted. This classification is as follows:

TABLE I

Average *B. Coli* per 100 c.c.

Class A +	0-10
Class A —	11-50
Class B	51-500
Class C	501-1,000
Class D	Over 1,000

The reason for the division of Class A into 2 parts is that it was desired to *work out a basis of comparison* with the classifications made on the basis of the sanitary survey, as described later, but, whereas it was felt that a line of demarcation could be drawn through the analytical results in this highest class, no such distinction could properly be made in the sanitary survey classification which groups the areas as A, B, C, and D. Of course, if desired, the distinction could be dropped and Class A + and Class A — could be grouped together as Class A.

A rough total of the entire length of Connecticut shore of Long Island included in this study is 181.3 miles. Following is a tabulation of the mileages and percentages of the total falling into each of the classifications on the basis of analytical results:

TABLE II

	Mileage	Percentage
Class A +	72.2	39.8
Class A —	43.8	24.2
Class B	33.7	18.6
Class C	18.5	10.2
Class D	13.1	7.2
Total	181.3	100.0

Reference is made to the manner of choosing sections of shore and the averaging of the *B. Coli* results at the included stations. This is given under the next sub-heading.

## ESTABLISHMENT OF SHORE SECTIONS

Principally on the basis of the sanitary survey data, but also with some regard to the analytical results, the shore was divided into sections varying in length from 1,000 feet to 1 or more miles. These shore sections were then classified according to the sanitary survey data and also according to the analytical data.

It is important to note that the classification of these sections both on the basis of the analytical data and also of the sanitary survey is the end point of this study.

The analytical classification of any particular section is made by averaging the results of the different individual stations included. The results for each station, as before mentioned, are secured by averaging the *B. Coli* counts for the 4 tidal stages. The sanitary survey classification, of course, was purely a matter of judgment by the engineers employed on the work.

## SANITARY SURVEY CLASSIFICATION

As has been mentioned, a sanitary survey classification of the shore areas was made. The sanitary survey included the location of sewer outlets along the entire shore with the accumulation of data as to the flows of sewage and contributing population. In connection with studies of shellfish areas in Greenwich, Norwalk, New Haven, and Bridgeport harbors, float studies were carried out by the State Department of Health in 1927 and 1928 and the results of these studies were available in considering bathing waters in these localities.

The sanitary survey classifications are: Classes A, B, C, and D. No A + or A — is included in the sanitary survey classification as this would seem to give a false impression of accuracy. Class A represents good conditions, as disclosed by the sanitary survey; Class

D represents very poor conditions on the same basis; Class B might be considered to represent fair to doubtful conditions; and Class C would include doubtful to poor conditions. The 2 intermediate classes are somewhat difficult of definition.

Following is a tabulation of the mileages and the percentages of the total, falling into each of the classifications on the basis of the sanitary survey:

TABLE III

	Mileage	Percentage
Class A	69.3	38.2
Class B	76.6	42.2
Class C	23 0	12.7
Class D	12.4	6.9
<hr/>		
Total	181.3	100.0

CORRELATION BETWEEN BACTERIAL AND  
SANITARY SURVEY CLASSIFICATIONS

Before proceeding to a discussion of the specific sections of the shore, it is of interest to present a tabulation showing the correlation between the classifications on the basis of analyses and the classifications on the basis of the sanitary survey information.

TABLE IV

Bacterial Classification	Sanitary Survey	Per Cent of Total
Class A +	Class A	36.3
Class A —	Class A	1.2
Class B	Class B	11.7
Class C	Class C	6.7
Class D	Class D	6.2
		<hr/>
		62.1

This table is of great interest in that a very close correlation is shown. The summary of the above percentages indicates that 62.1 per cent of the area studied showed an exact correlation.

In Table V are presented the data showing the variations between the bacterial and sanitary survey classifications

in the 37.9 per cent of the area where exact correlation was not found. A study of this table discloses that 36.7 per cent of the total area showed a difference of only 1 class in the 2 classifications.

The remaining portion of the total is but 1.2 per cent and this did not show a close relationship. In some sections falling in the last group, unexpectedly good bacterial results were secured in areas looking very questionable on the basis of the sanitary survey, and, conversely, poor bacterial results were secured in areas apparently free from serious pollution. The former discrepancy might be due to the laws of chance in sampling or to certain tidal movements or other reasons; the latter might be caused by some chance pollution by boats or due to concentration of surface wash entering the area from cultivated land.

TABLE V

Bacterial Classification	Sanitary Survey	Per Cent of Total
Class B	Class A	0.7
Class C	Class B	3.1
Class D	Class B	*1.1
Class A +	Class B	3.5
Class A —	Class B	22.9
Class B	Class C	6.0
Class C	Class D	0.5
Class B	Class D	*0.1
		<hr/>

\* Little correlation shown. 37.9

GRAPHICAL AND DETAILED PRESENTATION  
OF DATA

Office reports furnish detailed discussions of the conditions along various sections of the shore with a detailed tabulation of the areas.

For office use, the data have also been plotted on U. S. Coast and Geodetic Survey charts. Information concerning these data is available in the case of inquiries addressed to the State Department of Health.

## CONCLUSIONS

1. It is believed that the study of Connecticut shore waters has given a very satisfactory basis for classifying the sanitary condition of the various sections of the shore. While no sufficient basis exists for any system of absolute classification, such as "Good," "Fair," etc., a relative classification is possible and enough detailed information is available from the analytical results and the sanitary survey to enable the Department to answer intelligently most inquiries as to bathing areas along Long Island Sound. A very high degree of correlation is shown between the relative classifications of the analytical results used in this study and the classifications decided upon on the basis of the sanitary survey (or judgment).

2. Many miles of Connecticut shore were found to be in excellent sanitary condition, testifying to the great recreational asset the state has in her salt water bathing beaches.

3. The effect of harbor pollution in Connecticut is rapidly dissipated by dilution available in Long Island Sound so that the sewage from our cities and towns is not a factor, to any great extent, in polluting the main body of water in the Sound. The principal considerations are as to the harbor waters of themselves and waters in close proximity.

4. The harbors of many of our cities and towns are highly polluted and improvements are imperative. The effect of this harbor pollution exists also in waters in close proximity to our harbors. Unfortunately, it is these waters in and near our harbors that are frequently developed extensively for bathing because of their convenient nearness to centers of urban population. Some of our bathing beaches at such locations are close to the border line of safety. The salutary effects of

sewage treatment at these points are exemplified by the effects noted where treatment exists. The situation does not call for hysteria or undue alarm but a steady program of improvement along the lines now aimed at by state and municipal authorities should be followed.

5. The Housatonic and Connecticut Rivers, while subject to a large amount of pollution, undergo a great deal of self-purification before they enter the Sound, and the dilution available at their mouths is great enough to minimize the influence of pollution from these rivers so that they are no appreciable factor either in the pollution of much of the shore line or the main body of water in the Sound. This does not mean, however, that these rivers should not be improved in condition both with respect to certain tributaries and the rivers themselves where local and cumulative pollution is objectionable.

6. Numerous individual cases of local pollution were disclosed by the survey. Many of these pollution sources are of small magnitude but it is frequently the case that relatively small amounts of pollution in close proximity to bathing areas are more dangerous than far greater amounts at a greater distance. Coöperation of the public and better appreciation of desirable sanitary standards should gradually bring about improvements. The day is going by when the average citizen is content to build a house on the shore, pipe the household sewage to the water in front of the house, and then bathe in the water.

7. Increasing sewage pollution of our rivers and harbors will result in conditions more threatening to the safety of bathing beaches and shellfish areas in their proximity than may be shown by present studies, if not offset by installation of sewage treatment plants.

## FOOD AND NUTRITION

**Composition of Rabbit Meat—**These tests were made in the Bureau of Animal Industry of the U. S. Department of Agriculture. Four normal healthy domestic rabbits ranging in age from 10 months to 1½ years were used in the experiment. The animals were slaughtered and dressed in the regular way. The heart, liver, and kidneys were removed and weighed separately; the meat was then stripped from the bones and each weighed separately. The meat was prepared and analyzed in accordance with the official method of the Association of Official Agricultural Chemists. The composition of the meat was found to be similar to that of poultry, the content of moisture and protein being relatively high and that of fat rather low.—H. R. McMillan, *J. Home Econ.*, 23: 1149 (Dec.), 1931.

**Irradiated Milk: the Energy Requirements for Antirachitic Activation—**The radiation used in these experiments was obtained from various types of carbon arcs and mercury arcs operated under known conditions and with known energy. Fluid milk containing 1.2 per cent of butterfat was used, and the irradiation was carried out in 1,000 lb. lots. The milk was exposed to the radiation in the form of a moving film which received the rays at constantly changing cycles of incidence, varying from 0 to 90°. The periods of exposure were 8, 16, 32, and 48 seconds. The milk was immediately dried by the Just process and hermetically sealed in inert gas.

White rats, 28–30 days of age, were fed on the Steenbock and Black (*J. Biol. Chem.*, 64: 263, 1925) rachitogenic Ration 2965 for 21 days followed by 10 days of supplemental feeding of

10 c.c. daily of the reconstituted dry milk. At the end of this period the line test and bone ash determinations were made. The results show that substantially the maximum antirachitic potency which could be imparted to milk was brought about with the first few seconds of exposure. The objectionable flavor and odor so often reported as developing in milk after exposure to ultra-violet rays were not noticed.

Clinical tests were also made on 11 colored infants during the winter months. The infants were fully protected from rickets. The milk also showed definite curative value in a number of cases as shown by the marked healing in Roentgenograms.—G. C. Supplee, M. J. Dorcas, and Alfred F. Hess, *J. Biol. Chem.*, 94: 749 (Jan.), 1932.

**Protein Intake and Basal Metabolism of College Women—**Eighty-five women students, ranging in age from 19 to 37 years, 85 per cent being between 19 and 24 years of age, were studied in order to determine the habits of protein consumption and the possible relationship between protein intake and basal metabolic rate. The average protein intake was 0.94 gm. per kg. body weight, while the average protein intake of male students was previously shown to be slightly more than 1 gm. per kg. body weight (*Am. J. Physiol.*, 82: 577, 1927; 89: 403, 1929, and *J. Biol. Chem.*, 61: 109, 1924). The average 24-hour urinary nitrogen excretion for the group was 7.69 gm. It is suggested that the lower protein intake of women may be in part responsible for the fact that their basal metabolic rate is lower than that of men.—Rossleene Arnold Hetler, *J. Nutrition*, 5: 69 (Jan.), 1932.

**Staphylococcus Food Poisoning—**

The discovery of a new type of food poisoning due to the toxic products of staphylococci seems to explain a certain number of outbreaks in which no *Salmonella* bacilli are found.

In 6 recorded instances, staphylococci are quite well established as the cause of food poisoning. In 4 of these instances, food epidemiologically implicated contained large numbers of staphylococci. Pure cultures of these staphylococci yielded broth filtrates which, when swallowed in small amounts (2 to 10 c.c.) by human volunteers, produced symptoms noted in original patients. There are also 2 recorded instances in which staphylococci growing in milk have caused illness when swallowed by human beings. In 1 of the above cited instances, staphylococci of the albus type were implicated, yellow staphylococci of the aureus type being concerned in the other 5 instances. Other instances are cited in which staphylococci were the probable but not proven causative agents.

Differences in food poisoning due to staphylococci and that due to members of the *Salmonella* group may be found in the incubation period, mortality, and the amount of sterile broth filtrate which produces characteristic symptoms in human volunteers. In staphylococcus food poisoning the symptoms usually occur within 2 to 4 hours; no deaths have occurred in any of the above mentioned outbreaks or in approximately 100 human volunteers who have become ill after swallowing sterile toxic filtrates, and amounts as small as 2 c.c. of sterile broth filtrates of staphylococci will produce characteristic symptoms. In *Salmonella* food poisoning, the incubation period averages from 6 to 12 hours, with an estimated mortality of about 1 to 2 per cent, and *Salmonella* filtrates have been swallowed by human volunteers in amounts as large as 145 c.c. without producing characteristic symptoms.

Staphylococci concerned in food poisoning do not seem to differ culturally from the common and widely distributed members of this group. Toxin producing strains of both albus and aureus varieties have been found. Some strains may produce a toxin at one time and not at another. Their source is not known with any degree of certainty because of their wide distribution.

Further study of the properties of the toxic substance is in progress. There is no evidence of a true immunity to staphylococcus toxin although there appears to be some degree of tolerance. Repeated attacks may be produced in a volunteer by successive feeding. Boiling for 30 minutes does not destroy but perhaps weakens the toxin. Chlorination and storage at low temperatures do not destroy the toxic quality of broth filtrates.—Edwin O. Jordan, *J. A. M. A.*, 97: 1704 (Dec. 5), 1931.

**Does Freezing Kill Cl. Botulinum**

**Spores?—**The production and marketing of frozen vegetables and fruits without heat sterilization has raised the question as to whether or not there is a possibility of botulinus poisoning arising from the consumption of such products which had been improperly handled. Two general methods are used in the freezing of food products, "quick" freezing in which the food material is solidified in a comparatively short time by exposure to very low temperatures, ranging from  $-50^{\circ}$  to  $-85^{\circ}$  F., and "slow" freezing in which the packaged materials are placed in a refrigerated room and solidified only after several hours of exposure. Freezing the spores with solid carbon dioxide ice resembles the treatment in "quick" freezing, and exposure in a cold room is comparable with "slow" freezing. The effect of freezing upon the botulinus spores is obviously of first importance, and studies have been made in which the conditions of experimentation have

resembled those existing in commercial practice. Dried *Cl. botulinum* spores (Type B), suspended and heated in a Sørensen buffer solution of pH 6.9, have been frozen with solid carbon dioxide ice, defrosted at intervals, and the total numbers of living spores as well as the presence of toxin determined. There was no reduction in the number of living spores, neither when defrosted and examined immediately after being frozen, nor when they have been frozen for 9 days and then examined. Subcutaneous injections into guinea pigs showed that no toxin had been liberated from the spores by the freezing.

A suspension of dried spores of the same botulinus culture was divided among several test tubes and frozen by exposure in a refrigerated room held at approximately 20° F. Twenty-four to 36 hours were required for the suspensions to be thoroughly solidified. Examination of portions 1 day after being frozen and periodically to 11 weeks showed that there was neither a reduction in the total numbers of living spores, nor was toxin liberated.—Lawrence H. James, Abstr., *J. Bact.*, 23: 47 (Jan.), 1932.

**A Study of Escherichia Coli in Ice Cream**—This study was undertaken primarily to see if *E. coli* would survive pasteurizing temperatures in ice cream mix. Seventy-three samples of ice cream were examined and it was found that they contained from 200 to 157,000 bacteria per c.c. Forty-five samples produced gas and 21 produced a metallic sheen on eosin-methylene-blue agar. The majority of the samples were slow acid-producers in litmus milk. A Gram-positive organism was found that produced a metallic sheen on eosin-methylene-blue agar. When incubated in gentian-violet-lactose-peptone bile in combination with *Aerobacter aerogenes* and streaked on eosin-methylene-blue agar, it gave the partially confirmed

tests for *E. coli*. This organism is still being studied.

Two *E. coli* cultures survived 62.8° C. in milk; 13 cultures survived 62.8° C. in ice cream mix. At 65.5° C. 1 culture survived 3 trials out of 4, and at 68.3° C. the same culture survived 1 out of 4 heatings.

Sugar, gelatine, serum solids, and fat showed some protective action for bacteria in the order named. Heat-resistant *E. coli* showed a slight pathogenicity when given orally to guinea pigs. Dominick and Lauter liquid media seemed to be more satisfactory than Salle's.—J. Venceslav Anzulovic, Abstr. *J. Bact.*, 23: 56 (Jan.), 1932.

**Epidemics of Septic Sore Throat of Milk Origin; Present Status of Bacteriology and Epidemiology**—From studies made at the University of Illinois, College of Medicine, of septic sore throat, the following points seem to be established:

1. The epidemics are sudden, sharp and severe, indicating a massive dosage of the infecting agent.
2. The sick are largely limited to users of 1 milk supply. There are relatively few contact infections.
3. Epidemics rapidly recede when the infected milk supply is cut off or the milk pasteurized.
4. Usually 1 cow is found with an udder infected with an encapsulated hemolytic streptococcus. This organism produces large mucoid, watery, spreading colonies growing especially well on ascites blood agar. These organisms were observed in the Chicago epidemic of 1910–1911 and have become known since then as the *S. epidemicus*.
5. Experiments indicate that when these streptococci are implanted in the cow's teat, they will rapidly ascend the duct and localize in the udder, causing mastitis. They may continue there for long periods thus giving rise to the carrier state. The udder may or may not reveal gross physical changes.
6. Similar encapsulated streptococci are uncommon in the throats of normal persons (less than 1 per cent) but more common in infected throats (12 per cent of tonsils). Sporadic cases of septic sore throat indistinguishable from epidemic cases are occasion-

ally seen. From such throats encapsulated streptococci of the epidemicus type may be found.

7. These encapsulated streptococci produce toxins which give rise in animals to specific neutralizing antiserum. The toxins cause specific skin reactions in susceptible persons (differing from scarlet fever toxin). A study of several strains indicates that they are heterogeneous by the agglutination test. Agglutination tests however are often unreliable for encapsulated organisms. We have not as yet compared the toxin-antitoxin properties of a number of different strains.

8. From a study of many epidemics of septic sore throat, it appears that not infrequently cases of scarlet fever and erysipelas occur as complications. There is marked variation in this respect. At times scarlet fever and skin rashes are relatively common. Again they may be rare or absent and erysipelas relatively common. On the other hand it is well known that sore throat without rash

is common during epidemics of scarlet fever.

9. Strains of streptococci classed as scarlet fever or erysipelas organisms on the basis of skin and other tests at times develop capsules and grow quite like strains of *S. epidemicus*. Such strains may be the cause of milk-borne scarlet fever. The variability in these clinical manifestations together with the variability in properties of streptococci from epidemics of septic sore throat, scarlet fever and erysipelas suggest the possibility of a variable toxigenic and serologic property.

10. A study of the world distribution of epidemics of septic sore throat of milk origin reveals 3 general localities: namely, (a) Great Britain, (b) Scandinavia and Denmark, and (c) United States and Canada. In other parts of the world the methods of treating milk supplies may explain their freedom from infections.

—D. J. Davis, Abstr., *J. Bact.*, 23: 87 (Jan.), 1932.

## INDUSTRIAL HYGIENE

**Occupational Disease Clinic Established**—A weekly clinic for the benefit of labor and industry involved in occupational disease hazards has been established at the research hospital of the medical college of the University of Illinois in Chicago. Clinics will be held each Saturday from 12 noon to 2 p.m. The work of the clinic will be limited strictly to diagnosis and consultation. No treatments will be given.

Any person in Illinois of impaired health who has been exposed to any occupational disease hazard will be accepted at the clinic for examination. Occupations which involve these risks include painting, stone cutting, battery manufacturing and repairing, garage work, zinc smelting, varnishing, printing, lead mining, enameling and various others. Hospital facilities will be pro-

vided for those patients who need it.

The object of the clinic is primarily to make more easily available the special medical knowledge and facilities needed for the control and prevention of occupational diseases. Incidentally it provides a teaching center for medical students and for physicians who wish to specialize in industrial medicine.

The plan of operating the clinic is to work in close coöperation with industrial physicians and with the medical profession. It is anticipated that a diagnosis of lead poisoning, for example, or silicosis in any patient will lead not to appropriate treatment of the patient alone but to the application in the place of employment of measures calculated to minimize the risk to other employees.

The establishment of the clinic is the second important step taken re-

cently by the State Department of Public Health in its industrial hygiene program. A few months ago the McCord test for detecting the onset of lead poisoning was added to the diagnostic laboratory procedure provided by the Department.—*Illinois Health Messenger*, 3, 22 (Nov. 15), 1931.

E. R. H.

**Coal Miners and Tuberculosis**—Coal miners, although so constantly exposed to coal dust and stone dust, are notoriously less liable to pulmonary tuberculosis than workers in other dusty trades, and Haldane has pointed out that this situation has existed for generations. "It is difficult to resist the conclusion that in some way the inhalation of dust in coal mines tends to prevent phthisis."

The author suggests that this antituberculous property may depend upon the well known adsorptive power of coal dust and not upon any antiseptic action. Recent observations by the author and Dr. Weatherall have proved that coal dust in fine division can adsorb and inactivate tuberculin solutions to a marked extent.

When it is recalled that the lungs of silicotic and anthracotic coal miners may contain over one hundred grams of coal dust, as shown by Cummins and Sladden in their recent work, it will be readily conceded that the available adsorption potential of carbonaceous matter in silico-anthracotic lung tissues may be very great.

Accumulated coal dust in the lungs is not, however, an unmixed blessing. It leads to fibrosis and devascularization and sometimes to colloquative changes and even cavity formation so that emphysema develops with serious interference with respiration. Most old coal miners are dyspneic, although many work to a great age "short of breath" and suffering from copious sputum, cough, and sometimes asthmatic trouble.

While the collier's death rate from tuberculosis is relatively low, his death rate from "bronchitis" is very high. Possibly the word "bronchitis" is not well chosen. Coal miners possibly die from dyspnea instead of merely being dyspneic. Certain it is that stone dust and coal dust combined produce in time a state in which the breathing efficiency of the lungs is seriously compromised. The attitude of complacency commonly assumed toward the risks run by coal miners from exposure to mixed dusts is unjustifiable. Coal mining involves a definite risk of pneumoconiosis.

Two valuable lines of prophylaxis are open to further investigation: A closer study of the stone dust used to diminish the danger of explosions, and the reduction of dust from hard stone during the use of compressed air drills. The success attending the use of respirators against lethal gases during the late war encourages the hope that the risks in dusty industries may be as efficiently solved.—S. Lyle Cummins, *J. State Med.*, XXXIX, 9: 526-536 (Sept.), 1931.

E. R. H.

**International Conference on Industrial Accidents and Diseases**—This Conference held at Geneva, August 3-8, 1931, was attended by 450 delegates from many countries, including Australia, Japan, the United States, and South Africa.

The conference divided into 2 sections, for accidents and diseases respectively. The agenda included the following subjects:

1. Cutaneous affections viewed from an industrial standpoint
2. The influence of the previous state of health in regard to sequelae of industrial accidents and diseases, discussed by joint meetings of both sections
3. Traumatic lesions of the blood vessels (forms of arteritis and thrombophlebitis), and later sequelae and adaptation in cases of trauma

matic lesions of the spine, discussed by the accidents section

4. Pathology of workers in the cement and artificial stone industries

5. Receptivity of the system to toxic substances utilised in industry

6. Fatigue, discussed by the diseases section

More than 250 papers were submitted. An exhibition of photographic and radiographic slides, casts, and other graphic material was held in Geneva University.

It was decided to hold the next Congress at Brussels, 1935.—International Labour Office (League of Nations), *Indust. & Labour Inf.*, XXXIX, 10: 331 (Sept. 7), 1931. E. R. H.

**Health of Workers in the Engineering Industry**—Among the non-occupational health factors there are the general ones of good trade, regular employment, and decent earnings; the personal factor of physical health; and the environmental factor of home and its surroundings.

Among the occupational health factors characteristic of engineering are *sandblasting* in which oftentimes shot-blasting might be substituted with great decrease of hazard; *chromium plating* in which respirators and rubber gloves, aprons, etc., should be used; *cellulose spraying* in which the "pear-drop" odor of volatile amyl compounds and certain benzene derivatives occur; *oil dermatitis and boils* in which it is considered that a suitable bactericidal fluid for treatment of oil has been evolved; the *accident* relations especially associated with factors of temperature and humidity and the necessity for safety officers; and *fatigue* occasioned by excessive physical exertion or by monotony of work.

Rationalization in industry is a modern tendency; more and more work is being delegated to the machine. At the same time the machine and its tools should be constructed with regard to the physical comfort of the future op-

erative. Thus, the prevention of fatigue as well as of accidents depends upon the maintenance of psychological and physiological normality.—Arthur Massey, M.D., D.P.H. (Coventry), *J. State Med.*, 39: 10, 569-576 (Oct.), 1931. E. R. H.

**The Effect of Rhythm and Reverie on the Machine Worker**—Machine workers whose jobs permit the establishment of rhythmical bodily motions soon experience a "mind freedom," which permits protracted reveries.

Such reveries are often pleasurable mental excursions which leave the worker in an emotionally quiescent state. The triple combination of (a) response to measured cadence, (b) day dreaming, and (c) earning one's living accounts for great masses of human beings remaining contented year after year at work which requires only muscular attention. Bodily response to rhythm, and mental tendency to day dream, are among the oldest habits of man. When a human being engages in age-old customs, a sense of satisfaction usually accompanies such acts.

Machine made reveries may consist of nothing more than idle and fanciful musings or even morbid worries. On the other hand, they may be meditations of great merit. Samuel Gompers and Michael Pupin are examples of men who planned great things while they were still uneducated routine workers and later in life made imperishable contributions in their respective fields. Each in his autobiography clearly traces such deeds to the "mind freedom" permitted by certain work in their early lives. A number of other cases of reveries on the job are cited, among them being the experiences of the investigator himself while a conveyor worker at the Ford Motor Company plant.

The paper concludes with the suggestion of further research into the pos-

sibility of directing the mind habits of rhythmical workers into more generally constructive channels.—Stanley B. Matheson, *Ohio J. Sci.*, XXXI, 5: 425 (Sept.). 1931. E. R. H.

**Annual Report of the Commissioner of Industrial Alcohol**—This mimeographed statement for the press issued by the Bureau of Industrial Alcohol, U. S. Treasury Department, provides data concerning the production of alcohol, the manufacture of synthetic alcohol from ethylene during the past year on a commercial basis, the amount of alcohol and rum (149,303,438 proof gallons) withdrawn from bond for denaturation, and a table of the number of wine gallons of alcohol used in some 40 different manufacturing processes during the previous fiscal year. The number of permits in force as of June 30, 1931, was 177,833 divided between numerous manufacturing, business, educational, and medicinal usages (classified).

Modification of formulas for specially denatured alcohol have taken place following considerable research which has resulted in reducing to a minimum the illegal distillation of alcohol preparations for the purpose of obtaining potable alcohol. Weaker formulas were eliminated. On January 1, 1931, the bureau eliminated the use of wood alcohol in completely denatured alcohol; revoked completely denatured alcohol formula No. 1; and revised completely denatured alcohol formula No. 5 by replacing wood alcohol with *alcotale*, a new denaturant developed in the laboratory at Washington after several months of intensive research work. With the addition of *isopropanol* and *alpha terpineol* as additional denaturants to formula No. 5 and the addition of *alcohol*, the alcohol is rendered totally unfit for use as a beverage and impracticable for illegal recovery of potable alcohol.

The report mentions the extent of

the use of medicinal whiskey, rum and brandy products, distilled spirits, and wine, with a word about the issuance of basic permits which have now been standardized, and the control of plant operations. E. R. H.

**Tanning**—The extent and scope of the tanning industry in the U. S. and in the provinces of Canada is briefly summarized, after which conditions in 5 individual plants which were observed in field investigations are discussed.

A description follows of the methods of tanning, from the preparation of hides to dyeing and finishing. The general consideration of hazards, prepared by Dr. Carey P. McCord, takes up the different operations in order and the outstanding hazards. Among these latter are discussed synthetic tannings, anthrax, hydrogen sulphide, dyeing and coating, odors, pyogenic infections, and mechanical hazards.

As is usual with this series of reports there is a complete summary associating each particular occupation with its hazards, the list in this case involving some 100 different jobs.—Retail Credit Company, Atlanta, Ga., *Indust. Rep.*, VI, 12: 145-161 (Dec.), 1931.

E. R. H.

**A Survey of State Legislation of Interest to Physicians Since January 1, 1931. Changes in Present Compensation Laws**—An Ohio bill was passed adding to the list of compensable occupational diseases: manganese dioxide poisoning, radium poisoning, tenosynovitis and prepatellar bursitis, chrome ulceration of the skin or nasal passages, potassium cyanide poisoning and sulphur dioxide poisoning. A New Jersey law designates as "radium poisoning" that occupational disease hitherto listed as "radium necrosis" in the New Jersey act. Citation is made of a number of bills in various states which failed of enactment.—William C.

Woodward and Thomas V. McDavitt,  
*A. M. A. Bull.*, 26, 8: 202 (Nov.), 1931.

E. R. H.

**Functions of an Industrial Eye Clinic**—The benefits gained by industry through eyesight of employees are pointed out in a report just issued by the Metropolitan Life Insurance Company under the title "Functions of an Industrial Eye Clinic." This study further describes methods employed by leading industrial enterprises for supervising the visual conditions of workers through plant clinics.

"In almost any industrial plant where careful eye tests are conducted by an oculist, it will be found on the initial eye survey of employees that about 40 to 50 per cent have subnormal vision needing correction," the report states, and proceeds to describe the equipment and procedure necessary for correcting this condition. Several illustrated pages are devoted to a description of the technic of eye examinations, including a section on the many types of color blindness and recently devised methods of detecting it.

Particularly interesting to the industrialist is the chapter "Principles of Illumination" which tells about increase in productive efficiency traced directly to better vision. When the U. S. Public Health Service carried on a series of tests in the Post Office Department, it was found, the report states,

... that increasing the illumination from 2.7 to 10.7 foot-candles resulted in an increase of about 8 per cent in the number of pieces of small mail which could be sorted. . . . Investigations by Dr. M. Luckiesh indicate an increased speed of 15 per cent in reading ordinary printed matter for an increase of illumination from a value of 4 to a value of 16 foot-candles. For black print on gray paper the increase in speed was 50 per cent.

Discussing quantity, color, glare, and diffusion of light, the report sums up the subject by saying:

Among the advantages of good lighting in work places are greater accuracy of work, less eyestrain, increased production, less wastage, increased efficiency because of the greater ease with which work can be supervised, better order and cleanliness, and a reduction of accidents. A psychological effect may also be obtained through more cheerful surroundings due to good lighting, resulting in greater contentment and cheerfulness among workers.

The concluding chapter deals with Light Codes.—Policyholders Service Bureau, Metropolitan Life Insurance Co., N. Y. (1931).

**Tests Prevent Lead Poisoning**—During the 10 months ending with September, 1,040 blood tests for lead poisoning had been made in the Chicago branch of the diagnostic laboratories of the Illinois State Department of Public Health. Up through May, from 36 to 57 per cent of the tests made each month indicated marked absorption of lead on the part of the individual from whom the blood specimen was taken. This indicated that he was on the way to physical disability from lead poisoning.

Beginning with June the percentage showing a high degree of absorption has declined sharply. Of the 117 tests made in September, only 16 or 13.6 per cent showed a marked absorption.

Shifting employees to different jobs caused the change. Employees who were found to be absorbing lead at a significant rate were shifted to jobs where the exposure to lead poisoning was less or altogether absent.

This experimental work was made possible by the coöperation of a group of industrial physicians. Certain employees were chosen for the tests. Employment was shifted in cases that seemed to indicate the desirability of this procedure. The change in the tests suggests that this procedure was effective.—*Illinois Health Messenger*, 3, 21: 83 (Nov. 1), 1931. E. R. H.

# CHILD HYGIENE

## A STATE DIVISION OF INFANT AND CHILD HYGIENE

THE logical development of a Division of Child Hygiene in a State Board of Health is well exemplified in Indiana. Prior to 1919 sporadic attention was given to child hygiene, but in that year growing interest in the child culminated in the establishment of the Division of Child Hygiene. From the very first a comprehensive plan of organization was followed. The child hygiene work in that state has developed consistently year after year under the same general direction.

In July, 1922, federal assistance, under the Sheppard-Towner Act, was made available. For 7 years the Division of Child Hygiene carried out a consistent program that reached every county and township in the state. When the federal subsidy ceased, the momentum created by widespread health education and trained direction of child hygiene carried the activities through 3 trying years with but little slowing-up.

The administration of the Indiana Division of Infant and Child Hygiene has been under the able direction of Dr. Ada E. Schweitzer. The personnel of her Division consists of:

<i>Office:</i>	1 secretary
	2 stenographers
	1 artist-stenographer
	1 statistician
<i>Field Physicians:</i>	5 field physicians
<i>Field Nurses:</i>	6 field nurses
<i>Field Assistants:</i>	5 field assistants

### ACTIVITIES

The following health educational programs have been conducted:

1. County-wide child health conferences have been held for examination of infants and preschool children and for consultation with parents who bring their children to some central place in each community. Supervision by the family physician is advised and a parents' report card contains findings of the child hygiene division physicians. Routine advice concerning diphtheria, smallpox, and typhoid immunization is given. Special requests for examinations in one or more places in a county were granted if possible. One series of well baby clinics was conducted to demonstrate the value of periodic examinations.

2. A 5-period course in maternal, infant, and preschool care and in adolescent problems has been offered to adults, chiefly women, and to high school boys and girls. Lectures and demonstrations on growth and care of children were given to girls and women. The films reviewing the course were also shown to the young men.

3. Correlation of community health programs was encouraged. Assistance was given in planning programs.

4. Exhibits including poster groups, table displays, and pamphlets and books were available on request. A special exhibit was prepared for the American Public Health Association and one for the American Medical Association, and for the State Medical Association and State Health Officers Conference, the State Parent-Teachers, Federation of Women's Clubs, and many other national, regional, state, and local associations.

5. Motion pictures were planned for meetings of state and local organizations, for schools, churches, and clubs, and for other local programs.

6. Lectures and practical talks were given on growth and care of children.

7. A weekly health education talk was broadcast from station WFEM, one talk from station WKBF, and two from WLS.

8. Gorgas Memorial Association feature articles were prepared for publication.

9. Health projects were planned in personal conferences.

10. Programs were prepared to be carried out by state-wide groups.

11. Health pamphlets were distributed.
12. Special projects designed to instruct large groups, as the parent education program at Winona Lake, the State Fair better babies demonstration, and college classes, were conducted.
13. Staff schedules and state-wide Child Health Day programs were organized.

#### GENERAL WORKING PLAN

"Wherever possible county and township chairmen assisted in organization for any type of activity. They were selected from groups having county-wide organization. Local health officers, nurses, physicians, school officials, and lay groups usually assisted the state child hygiene workers."

Each field staff organizes and conducts conferences, classes, and other health projects. Special organization is planned for such activities as Child Health Day, state fairs, and parent education institutes.

The major activity for the year 1929-1930 was the child health conferences, in the preparation of which the field staffs visited 35 counties and 190 towns.

#### EDUCATIONAL PROGRAM

"The most outstanding part of the educational program, the class instruction to women and to high school girls and boys, includes lectures by a child hygiene physician, demonstrations by the child hygiene staff nurse, and exhibits of health posters and charts, and motion pictures.

"During the past year this instruction has been given largely to high school girls, with suitable health films for boys, who have shown a splendid attitude and much interest. Always the work is adapted to the type of group receiving it. The high school girls ask

questions, take notes, and are generally alert to all that is offered them."

The annual reports of the Division of Infant and Child Health are replete with valuable suggestions and analyses of extensive data.

#### PRENATAL CARE

The studies made of examination records by members of the staff reveal conditions which should interest every health official. For example, a history of prenatal care, based upon the records of 7,311 women who brought children for examination to county conferences, showed the following:

- 22.0 per cent had no prenatal care
- 3.4 per cent had 6 weeks or less
- 24.0 per cent had 6 weeks to 6 months
- 50.5 per cent had 6 to 9 months

"A study of the percentage of women who had abnormal labor would indicate that many women consulted their physicians because of abnormal conditions and that many others did not consult physicians because no alarming symptoms appeared. At any rate, the highest percentage, 91.7 per cent, reporting normal labor appears in the group having no prenatal care."

#### IMMUNIZATION

"The proportion of children immunized to one or more diseases is improving. Last year histories of children examined showed 1 in 5; this year the ratio is 1 to 4.5. These are chiefly pre-school children who are brought to county child health conferences for examination. Indiana parents generally do not as yet understand the importance of diphtheria immunization under 1 year."

# PUBLIC HEALTH NURSING\*

**The Hospital Nursing School and Economics**—Cost studies of nursing schools are coming in to the Grading Committee. Of 111 hospitals which figured what it would cost them to give up their schools, 19 would save money, 92 would lose money. In this study, for every 10 students let go, 18 per cent of the hospitals would need (plus maids and orderlies) 0-3 registered nurses; 19 per cent would need 4; 28 per cent would need 5; and 35 per cent would need 6 or more registered nurses. If giving up their schools, 40 per cent would reduce the teaching and supervisory staff; 50 per cent retain the same number; and 10 per cent would add to their number.—Take Out the Profit, *Am. J. Nurs.*, XXXII, 1: 54-55 (Jan.), 1932.

In this connection it is interesting to note that a letter from J. C. Geiger, M.D., Health Officer for the City and County of San Francisco, Calif., to the American Public Health Association, states that on January 1, 1932, the San Francisco Hospital closed its nursing school and thereafter would employ only graduate nurses to care for its patients. Dr. Geiger writes:

The Committee on the Grading of Nursing Schools has found that the number of schools and the number of graduate nurses is out of all proportion to the public demand. The Department of Health, in closing its undergraduate school of nursing, has been mindful of the overproduction of nurses, with their resultant unemployment and has welcomed the opportunity to assist in adjusting this economic situation.

In opening the hospital to a postgraduate school of nursing the administrators feel that a definite contribution will be afforded the

community by the opportunity offered for advanced training in the special fields which are available at the San Francisco Hospital. Advanced courses in children's diseases, maternity, operating room technic, tuberculosis, and communicable diseases, are now outlined with the development of special courses in ward administration, genito-urinary diseases and psychiatric nursing proposed for the near future.

**Do You Know What an Hourly Nursing Service Is?**—Nurses themselves have been responsible for the hourly nursing service movement because it seems to offer one solution of the problem of how to reduce the cost of illness. Yet despite the fact that this service is badly needed in most communities, and is available in many urban communities and in some towns, and even in rural centers, it is growing rather slowly in popularity. Either patients do not know about it or no one remembers to suggest it.

An article by Miriam Ames in the December, 1931, *Hygeia*, entitled "Fifty Ways to Use the Hourly Nurse," explains this service so clearly and completely that the American Nurses Association, 450 Seventh Avenue, New York, has had reprints made which can be obtained from their office at a cost of 5 cents each. There ought to be a big run on these pamphlets.—Miriam Ames, *Fifty Ways to Use the Hourly Nurse*, *Hygeia*, IX, 12: (Dec.), 1931.

**Public Health Nursing in New South Wales**—New South Wales is the oldest Australian state. Its area is somewhat greater than that of Texas and its population about half as large.

In 1912 there was only 1 trained nurse employed in public health work in New South Wales; there are now 215, including those employed by the gov-

\* Please send printed matter or other material relating to public health nursing to Eva F. MacDougall, 6 West Hulse Annex, Indianapolis, Ind.

ernment and by private or unofficial agencies.

*Nurses Employed by Official Agencies*—The Department of Infant and Maternal Welfare employs 111 nurses with a supervisor.

The Tuberculosis Division of the government employs 2 trained nurses who have also the certificate of the Royal Sanitary Institute.

The Department of Education (Medical Branch), under the direction of the Medical Director of Education, employs 13 nurses.

*Nurses Employed by Unofficial Agencies*—There are 41 Bush Nurses scattered in different parts of New South Wales—the organization which finances them receives a small government subsidy.

The District Nursing Association, which is supported by private subscription and subsidized by the government, employs 12 nurses who visit the sick poor in their homes.

The Royal Prince Alfred Hospital has 2 nurses who visit tuberculosis patients. The Fenwick Hospital employs 6 visiting nurses, and the children's hospital 1.

The Lactogen Company employs 1 nurse.

There are 5 nurses employed by the Plunket Association, who give advice to mothers according to the teaching of Sir Truby King, under the direction of a supervisor.

There are 17 industrial nurses employed by private firms.

Dr. J. S. Purdy, M.D., Medical Officer of Health for the Metropolitan Combined Sanitary Districts, with headquarters in Sydney, is studying and seems to be very much interested in generalized public health nursing services in other parts of the world. He has a keen

grasp of what this type of a service could mean for he writes:

General public health nursing in contradistinction to "specialized" nursing, means simply that nurses are assigned to general nursing work of all kinds in small districts instead of being assigned as individuals or groups to special nursing activity on a city wide basis. Generalized nursing in its broadest sense includes not only instructive nursing but bedside nursing as well. It is difficult to separate instructive nursing from bedside nursing because in many cases the success of the health nurses' effort to instruct and advise is contingent upon her helpfulness in actual care of the sick patient. When a member of the family is sick, the nurse who is prepared to do something tangible for the comfort of the patient is better able to get a hearing on other health matters. It often happens that her success in preventing disease depends on her care and management of the individual during illness.

The natural tendency in the organization of health nursing activities is toward specialization of nursing assignments in various fields of communicable disease work, school health work, prenatal work, infant welfare work, etc. Although the nurse specialist acquires a technical skill in dealing with these special activities which she could not acquire if her duties were of a more general character, specialization in public health nursing tends to considerable overlapping and duplication of work and prevents the nurse from acquiring a well rounded view of the many sided problem of community health. Then, too, the nurse should be a public health nurse instead of a communicable disease nurse or a tuberculosis nurse, child welfare nurse, or what not, for as a knowledge of public health needs has grown, it has become apparent that to deal effectively with the individual "case" of sickness the health visitor must be capable of dealing with a great variety of related problems in the home.

—*"Nurses Employed in Public Health Work in the State of New South Wales"* and *"Generalized Public Health Nursing,"* by J. S. Purdy, M.D., Medical Officer of Health for the Metropolitan Combined Sanitary Districts of the State of New South Wales.

## EDUCATION AND PUBLICITY\*

Is There a Plan?—The wide range of press release topics issued by different states during the same period is quite puzzling. To a degree they reflect department programs, but that does not fully account for the diversity.

Are there plans for a progressive development of subject matter, with due allowance for seasonal topics and emergency matters?

Are press releases accompanied in some states by corresponding plans for other forms of presenting the same topics?

Are meeting topics offered to local groups? Suggestion of the press topics for use by speakers?

Are there plans far enough ahead so that local meeting programs could be planned for the weeks when certain topics are to be presented in the newspapers?

Are such plans desirable? Are they practicable?

Are such questions as the above worthy of detailed consideration by state and local health workers?

Says *Mind and Body* in a recent issue:

Teaching without a program is like sailing a boat without a compass—one just goes without knowing where.

*They Are So Varied*—Omitting releases on departmental activities or announcing or reporting meetings, here are the topics of material supplied recently to the newspapers by state and national departments of health:

*Connecticut*: "Survey of Indoor Pools"; "Can Smallpox be Controlled by New Year?"; "Conserving Eye-

sight"; "Smallpox Again"; "Smallpox Vaccination Necessary"; "Christmas and New Year Greetings"; "Health Officials Concerned in Protection of the Public Health."

*Iowa*: "Christmas Greetings" (to editors, nurses, teachers, and organizations); "Christmas Presents" (diphtheria prevention); "Trichiniasis"; "Opportunities—And Resolutions"; "From Pail to Palate"; "Tularemia"; "Dangers Associated with Decreased Appropriations."

*Maryland*: "Read the Labels" (on holiday food flavorings); "Christmas Presents" (diphtheria immunization); "Regulations in Regard to Anti-Freeze Mixtures"; "What They Do" (bacteriological laboratories); "Last Year's Record"; "Facts and Fallacies" (mouth hygiene); "The Maryland Family"; "What and When and Why" (paragraphs of public health news); "Tune In on Station KYH" (Keep Your Health).

*New York*: "Leisure and Health"; "Pneumonia a Preventable Disease"; "Trends in Mental Disease"; "Football and Health"; "Athlete's Foot"; "Climate and Tuberculosis" (all radio).

*Oregon*: "Pneumonic Danger"; "The Double-Barred Cross of the Christmas Seal"; "What is a Public Health Nurse?"; "Contagious Sores." Every weekly press release is accompanied by tabular "Report on Communicable Diseases" (no comment). "Moist Air Necessary for Health"; "Immunize Early Against Spotted Fever"; "Every County and City Needs a Health Department"; "Hand Washing and Communicable Diseases."

*Virginia*: "Cleanliness in Surgery" (radio).

\* Please address questions, samples of printed matter, criticisms of anything which appears herein, etc., to Isaac G. Koutzko, 139 E. 22d St., New York, N. Y.

*U. S. Public Health Service:* "Health Conditions in the United States" (1930-1931); "Prevention of Cancer"; "Present-Day Problems of Yellow Fever"; "Health Conditions Throughout the World"; "Items of Historical Interest Relative to Pellagra in the U. S."; and the following broadcasts: "The Care of the Teeth"; "Public Health Nursing"; "Starting the New Year Right"; "The Health Problem of the American Negro"; "Remarkable Remedies from the Endocrine Glands."

**Is Any Department Too Small?**—Too small and lacking in funds to get out its own house organ or health bulletin? The spread of mimeographed bulletins suggests that a department or other health agency need not be without a bulletin *if it has something to tell the public in that form.*

In small cities and towns, especially, so much can be asked of volunteers. We know of bulletins of welfare agencies which are mimeographed in some business office without cost. Volunteers may be secured for the folding and mailing. The actual cash outlay could be limited to postage, envelopes and mimeograph paper. Ready-stamped envelopes will reduce cost and labor.

Possibly the important question to be settled is: "Have we anything to say which could be said better through our own bulletin than through the newspapers?"

**Uniformity with Variety in Reports**—What Illinois has been trying:

Before the preparation of the annual report for 1930-1931 of the divisions of the Department of Public Welfare was started, the department called together a committee of managing officers for the purpose of outlining a plan which would produce a better standard of report. . . . The committee were unanimous that a hard and fast outline which

every institution would be required to follow should be avoided. It was the opinion of all that each institution should have latitude to express itself. At the same time, it was felt that there was certain information common to all institutions of the class, which should appear in the annual reports. Accordingly the committee set up those subjects on which each institution should be expected to make a report. Among these were: movement of population and personnel; medical department; research and education; occupational therapy; recreational therapy; diet; dentistry; nurses; attendants; paroles; farm, garden and dairy; schools; repairs and improvements; cemetery; and recommendations.

**How to Select Posters for Classroom Use?**—A revised edition of *Some Posters on Child Health* (American Child Health Association, 450 7th Ave., New York. *Free*) says:

When selecting published posters for the schoolroom, consider these points:

Will they be of assistance to the teacher and to the child in initiating activities?

Are they of sufficient interest to the child to affect his behavior?

Will they increase his understanding of healthful living?

The most effective use of a poster is as an illustration of some definite health lesson, or as a stimulus to the practice of a health habit that has already been discussed. Simply to hang a poster on the wall and expect it of itself to bring about an improvement in health practices, is to ask too much of the poster or the child.

Probably more effective than any printed posters are the ones worked out by the children themselves as an expression of the health ideas they have formed.

**Undated Publications**—For libraries, for students, for writers, and for other readers it is often important to know the date of a publication. And frequently the date is of first importance and so should be easy to find. Here is an important statement on "The Care of Mental Defectives in New York State." *At what date?* Half way through we find "(in 1929)"

—which may or may not indicate data suitable for a given purpose.

*Please date your printed matter*—at front or back—for the sake of your readers, or some of them.

**Average Attendance of 2,000—**That is the record of the first series of public lectures given by the Health Education Foundation of the Cleveland Academy of Medicine. A nucleus of \$10,000 was provided by the Academy.

When recommending the Foundation the Committee on Health Education cited the following possibilities:

1. To apply scientific research to present health education methods and material to test their worth and effectiveness.
2. To provide public health lectures, carry on publicity in the interest of health through paid space in publications, through radio broadcasting, through group or individual instruction, and through other means as conditions may warrant.
3. To acquaint the public with all the advantages the community offers in the way of caring for the sick and the prevention of disease.
4. To seek to increase observance of the laws, ordinances and statutes affecting public health.
5. To urge the adoption and enforcement of legislation in the interests of health.
6. To advise the public against exploitation.

The *Bulletin* of the Academy (April, 1931) says:

Criticism has been aimed at much of the health education propaganda in the past. Much of the criticism has been based on ignorance, but some has been justified. Probably, the two greatest failures have been lack of intelligent direction and lack of funds. As the *Plain Dealer* phrased it, Health education has been the "Orphan Annie" of many institutions. Being merely an adjunct of larger programs (usually service programs), it has received short shrift as far as the dollars available are concerned.

The Foundation is, so far as we know, the first attempt to put health education on an endowment basis. There are, of course, endowments for specific fields of activity, but none solely for the study and propagation of education in the active field of public health. Therefore, its importance is more than local.

**The Ability to Plan—Says Dr. J. Mace Address:**

The ability to plan is one of the first qualifications of a health educator. What are your most pressing needs in health education? What plans will you formulate for the New Year?

Dr. Address urges extensive health education planning, by school systems, by single schools, by individual classrooms.

How a plan may be directed at a simple objective is illustrated:

Let us suppose that the prevention of colds is to be the goal of a health program in a certain school. This is an illness that leads all others in most schools. The principal or health teacher who is to initiate this program should first get the coöperation of the teachers, school doctors, school nurses, and parents. A program if it is successful should be understood and approved by all those who come in contact with the children. It might be well to have the whole matter brought up before a parent-teacher meeting. Coöperation of the parents is especially necessary in this project, since most colds are communicable; children should be encouraged to stay at home at the onset of a cold. More sleep, rest and attention to hygienic living are desirable. These are not to be gained ordinarily unless parents and children work together. Through health teaching the school may hope to guide and motivate children in the right way.

Although the prevention of colds may seem at first to be the only objective it is easy to see that the carrying out of such a program would involve almost every aspect of healthful living. Although there is still much to be learned about colds it is obvious that we know enough so that with united efforts they cannot only be reduced but those contracted may be less serious.—

Should We Adopt a Five Year Program for Health Education? *Hygeia*, Chicago. Jan., 1932. *Sample free.*

**Single Samples Only—**Sample copies are usually available, but readers will be disappointed if they ask for quantities of material issued by state and local agencies.

If you want more copies it is safe to ask the price.

**Many Questions Answered**—To help answer letters of inquiry from teachers, public health workers and others a group of tentative memoranda has been prepared and is being submitted for criticism and suggestion. Copies of the tentative memoranda will be sent to those who will promise to write out their criticisms and suggestions. When issued the revised editions will be offered to all who care for them. Here are some of the titles:

Sources of information on health education problems and methods in elementary schools; health education: free material for distribution to pupils; posters: hand-made or school-made; posters: in school health education; plays: health; marionettes: puppets.

**Thin Ice**—Leaders in the nursing profession have been aroused by the use of the uniformed nurse in advertisements, and direct testimonials for merchandise signed by nurses. "New Ethics in Publicity," by Meta Pennock, A.B. (*Trained Nurse*, 468 4th Ave., New York. Dec., 1931. 35 cents) is illustrated by numerous advertisements in which the nurse is featured.

Strange as it may seem in 1932 there was a time when the medical profession—

and the nurse interpreter kept their wisdom to themselves with the idea that science was much too complicated to be interpreted to the lay mind—and at times the accompanying idea that if this knowledge were common property they would have less standing professionally and less profit financially. . . .

Swept in by the public health group came the new attitude—that the teachings of science should be reduced to their simplest terms so that all might apply them with the degree of understanding which each possessed. From this standpoint all the sound information on health habits and healthy living which can be conveyed through advertising in magazines, on the radio, or in the writings on the sky is that much benefit to the public. Carried on this tide of helpfulness and freed from the narrow-shouldered type of ethics of the previous generation, the physician has stepped out of his office into the public forum. The nurse,

who is his interpreter and his extender, has followed suit, and is showing by precept and practice how science may be applied for the prolongation of life and for its enrichment. . . .

Miss Pennock discusses the dangerous situation when a nurse gives a health talk on time purchased by an advertiser.

First she should ascertain from reliable sources the standing of the organization under whose auspices she is asked to speak.

A list of the sources of information follows with a reminder to consult—

local scientists in good standing—doctors, health workers, public health nurses and others as to the content of the address to be delivered.

The nurse's responsibility to the public and to her profession forbids her to include—

any endorsement or testimonial of the product or products of the manufacturer or dispenser who sponsors the broadcast. She must also exact the promise that she be permitted to read in advance and approve of every word of the announcer or continuity speaker who carries the program with her. This prevents her talk from being coupled with unwarranted or exaggerated claims for the product and avoids the possibility of giving the impression that she endorses the organization or its products.

The advice about giving testimonials is quite positive.

This question of written, spoken or implied endorsements or testimonials can be handled in but one way: Like that famous advice to those about to marry, the answer may be summed up in the one word, "Don't." European professors of medicine who are sorely in need of money to continue their researches may step out of their scientific frames to recommend yeast, antiseptics, or soap, but in America it "just isn't done." Good ethics throws down the challenge of placing the public in a vulnerable position.

Praise of the nurse-speaker is to be guarded against by careful examination of all introductory speeches.

With the permission of those organizations with which she is associated—the local hos-

pital, the local visiting nurse's association, etc., these connections may be mentioned because they tend to give the public confidence in the health information which she will impart. The university from which she obtained her general education and the nursing school from which she was graduated, as well as membership in professional or educational bodies, are also clues which the public seeks in its effort to measure the degree of authority or scope of knowledge of the person whose health advice is to be followed. She speaks, therefore, not as an individual but as a representative of every group mentioned and her responsibility as such a representative is thereby increased a hundred fold.

The article continues with a group of dilemmas faced by physicians, nurses and research workers, and how they met them. "Was this ethical, was this protecting the public?" is asked of each case.

These examples touch upon the writing of booklets and other material, both signed and unsigned. Miss Pennock draws her own conclusions, and points to the recently published code of the New York Academy of Medicine and the Medical Society of the County of New York as a further guide.

#### NEW

*Better Times*, long published as a miniature magazine record of health and social welfare in New York City, is now issued by the Welfare Council, 122 East 22d St. The page size is now larger; weekly news issues, with four magazine issues a year. *Sample free.*

*By The Way*, Health Education Division, Children's Fund of Michigan, 660 Frederick St., Detroit. Mimeographed bulletin.

*New Mexico Health Officer*, State Bureau of Public Health. 9 pp. Mimeographed.

#### HONORABLE MENTION

To Merrill-Palmer School, Detroit: For biennial report with both contents and index.

#### RADIO

Boston has been broadcasting over WEEI a series of conversations on White House Conference subjects. Frank Kiernan, Dr. Raymond S. Patterson and Dr. Lila Owen Burbank have exchanged questions, argued, agreed or disagreed via radio.

"Hydrophobia" and "Explorations in Nutrition" were recent topics broadcast by Dr. Haggard Sunday nights. *No charge* to receive printed copies weekly. Address Eastman Kodak Co., Rochester.

Present and Impending Applications to Education of Radio and Allied Arts is a revised edition of one issue of the Information Series of National Advisory Council on Radio in Education, 60 East 42d St., New York. Presents, intelligibly to the layman, the mechanical and other scientific conditions and problems in broadcasting, television and sound pictures; definitions of terms. *Free.*

Five-minute broadcasts on mental hygiene, 20 of them, with 8 on child guidance, are reprinted in Radio Talks on Mental Hygiene and Child Guidance. New York State Dept. of Mental Hygiene, Albany. 54 pp. *Free.*

The "world's biggest gymnasium class" is now directed over stations WEAf, WEEI, WGY, WBEN, WRC, WCAE, WFI, and CKGW. Daily, except Sundays and holidays, at 6:45, 7:00, 7:20 and 7:45 A.M. Self-Directed Body-Building Drills is 8-page illustrated folder supplied free by Tower Health Broadcasting Station, Metropolitan Life Insurance Co., New York.

Quite a series of mimeographed copies of broadcasts will be supplied by Bureau of Health Education, Dept. of Health, 139 Centre St., New York. *Ask for a list.*

Various radio talks are reproduced in *Monthly Bulletin*, Philadelphia Dept. of Public Health, *Connecticut's Health*

*Bulletin* (State Dept.), and *Pittsburgh's Health* (Dept. of Public Health).

Baltimore Health Dept., in collaboration with the Medical School of University of Maryland, has inaugurated weekly broadcasts over WBAL, Tuesdays at 6:15 P.M.

New York State Dept. broadcasts over WGY are now given on Wednesdays at 6:15 P.M.

#### DEPRESSION

What are the results of unemployment and depression conditions upon health, both now and in the future?

Please send your impressions, your observations, your fears.

Have you any statistical data, or are you planning to gather any?

"Do Hard Times Harm Health?" Notwithstanding the statistics as given out by Surgeon General Cumming, dare we ignore such statements of fact as the one given out by the United Hospital Fund of New York? *American Medicine*, New York. Nov., 1931.

"Unwise Economy to Curtail Health Services." Statement in *Health News*, New York State Dept. of Health, Albany.

This is a time when nutrition is again a news topic. Under the leadership of the Food Administration during the war, balanced diet and suitable food for various age groups was spread far and wide, using food saving as a peg on which to hang information. In the present emergency again, economical balanced diet is of major interest.

"Emergency Nutrition Special" of *American Child Health News* (clip sheet), 450 7th Ave., New York (Jan., 1932), gives material for house organs and other uses. *Free*.

"What best to do with an inadequate amount of money?" is answered simply and practically by H. C. Sherman, Columbia University, in *Child Health Bulletin*, American Child Health Assn., 450 7th Ave., New York. Nov., 1931. *Free*.

The Connecticut State Dept. of Health has reprinted the above as a 4-page folder.

Somewhat the same information is expressed even more simply and more graphically, in form for popular distribution in *Getting the Most for Your Food Dollar*. Bureau of Home Economics, U. S. Dept. of Agriculture, Washington. *Free*. Reprinted in *Red Cross Courier*, Washington. Feb., 1932.

"Food and Nutrition in the Depression Period." Editorial in *J. A. M. A.*, 535 N. Dearborn St., Chicago.

#### SPECIAL EVENTS

Ask for celebration material, addressing U. S. George Washington Bicentennial Commission, Washington Bldg., Washington, D. C.—if you wish to give a health angle to the celebration.

May Day—Child Health Day is not far away. For suggestions address American Child Health Assn., 450 7th Ave., New York.

National Negro Health Week comes April 3–10, 1932. Supplies need to be ordered quickly. Last year half the orders were sent in too late to print large enough editions. Posters and Negro Health Week Bulletin each sell at \$1.25 for 100, \$12.50 for 1,000. Order of Superintendent of Documents, Washington, D. C.

#### CONTESTS

*Journal of the Outdoor Life*, 450 7th Ave., New York, offers prizes for mystery stories. "Must be strictly mystery stories, not necessarily murder stories. . . . Tuberculosis must in some way be connected, though the setting may be anywhere." Closes April 1, 1932. *Write for details*.

Awards for essays and plays or pageants offered to schools of nursing and members of district associations by American Nurses' Assn., 450 7th Ave., New York. Closes May 1, 1932. *Write*.

Posters on fresh air are to be judged for prizes by Anti-Tuberculosis Society, 207 N. Centre St., Pottsville, Pa. The classification and rules will be *supplied on request*.

Hundreds of talks were prepared by high school students last year for the radio public speaking contest conducted by the Minnesota Public Health Assn., St. Paul. Nearly a hundred talks were selected in preliminary contests before high school assemblies. Ten talks, in the final contest, were broadcast by the students on consecutive days. A similar contest is now under way.

#### EDUCATIONAL

Educational effort among special groups often may prove more significant and far-reaching in its influence than some more appealing and even spectacular efforts to reach the general public. Other health workers, social workers, key men and women in the varied clubs, professions and other groups, make up some of these special audiences.

From month to month time may be taken to advantage for mailing a few copies of highly specialized publications to very carefully selected names.

Much of the material listed below is useful for such specialized educational effort.

Adequate County Health Organization, Tuberculosis Control and the Medical Profession (13 pp.); Medicine: The Tortoise—Why Pick on It? (equals 7 pp.). By D. D. Armstrong, M.D. Metropolitan Life Insurance Co., New York. *Free*. Reprints.

The Frontier Nursing Service, by Anne Winslow. Committee on the Costs of Medical Service, 910 17th St., N.W., Washington. *Free*.

Income From Medical Practice, by

R. G. Leland, M.D. American Medical Assn., 535 N. Dearborn St., Chicago. Reprint. 24 pp. *Free*.

The Newer Aspects of Anti-Tuberculosis Work, by Iago Galdston, M.D. Address the author: New York Academy of Medicine, 2 East 103d St., New York. 11 pp. Reprint. *Free*.

Principles and Problems of After-Sanatorium Care, by Edw. Hochhauser. Address the author: Committee for the Care of the Jewish Tuberculous, 71 West 47th St., New York. 10 pp. *Free*.

The Coming Baby (22 pp.); The Care of Baby (34 pp.); Food—The Teeth and Health (30 pp.). Substantial pamphlets; simple illustrations—the third one with color. To be issued: The Pre-School Child. Dept. of Health, 139 Centre St., New York.

Smallpox and Vaccination: Information for Physicians. Connecticut State Dept. of Health. 8 pp. *Free*.

Your Emotions; Behavior Patterns; and 12 other 4-page folders. New York State Dept. of Mental Hygiene, Albany. *Free*.

Books for Parents, Teachers, Social and Public Health Workers; For Your Home Library; A Selected List of Social Hygiene Publications; Free Folders and Leaflets. American Social Hygiene Association, 450 7th Ave., New York. *Free*. Lists of publications.

The Prudential Insurance Co., Newark, N. J., offers booklets and folders on exercise, smallpox, diseases of children, food, tuberculosis, child health, first aid, common drinking cup, cancer, hiking, and "Our Babies." The last is the large illustrated pamphlet by Dr. H. N. Bundesen.

Safety and Simplicity in Infant Feeding; A Safer World for Babies. Evaporated Milk Assn., 203 N. Wabash Ave., Chicago. *Free*.

## BOOKS AND REPORTS

*Proceedings of the National Conference on College Hygiene—Sponsored by the President's Committee of Fifty on College Hygiene, The National Health Council, The American Student Health Association. New York: National Tuberculosis Association, 1931.*

This report, just issued, is one of the most arresting which has come to our attention in a long time. In view of the fact that there are upward of 1,000,000 students in our universities, and that these are in a formative period of life, the importance of the subject may be appreciated.

The report does not lend itself readily to review, consisting as it does of reports by sub-committees which have been carefully edited and are succinct.

We may mention as outstanding features the conclusion that every college, regardless of size or resources, is under obligation to make arrangements for the protection, maintenance and promotion of the health of its students and the treatment of those physically or mentally sick or socially maladjusted. The educational purposes of a college are not adequately served when there is lack of arrangements for instruction concerning maintenance and protection of physical, mental, and social health. Tentative rules are given for the carrying out of these fundamental propositions. All college health teaching and physical welfare activities, including health service, physical education, and intercollegiate activities, should be conducted under one administrative unit, or equivalent. Among other procedures, the routine Wassermann test is advised. The common cold is a most important factor in morbidity, and should not be lightly

considered as at present. Early and intensive treatment is required.

A special report was made on tuberculosis. A complete history of all new students, physical examination and routine tuberculin tests (Mantoux intradermal), with X-ray pictures of all giving positive reactions, which should be repeated if suspicious signs should appear, are advised.

It is held that it is a fundamental responsibility of a college to limit its use of the interest from its trust funds and other financial resources to the education of students whose intellect, health, and personality give reasonable assurance that the educational investment will not fail because of early incapacity or premature death.

We know of no publication which gives in so little space such a clear exposition of the underlying fundamentals of college health, the responsibility of college authorities, combined with putting an outline for the recommendations into effect. MAZÏCK P. RAVENEL

*Examination of Water—By William P. Mason and Arthur M. Buswell (6th ed.). New York: Wiley, 1931. 224 pp. Price, \$3.00.*

This sixth edition of Professor Mason's well known textbook, *Examination of Water*, revised and enlarged by Professor A. M. Buswell, bears a worthy testimony to the esteem in which previous editions of this book have been held. Chapters are presented dealing with: (1) chemical examination of water, (2) routine laboratory methods for the estimation of mineral constituents, (3) laboratory exercises in water treatment, and (4) the bacteriological examination of water.

In revising the text, new methods, such as the determination of hydrogen ion concentration and the use of eosin methylene blue agar, have been incorporated; the wording and terminology in certain instances have been modernized; and the appendix has been extensively enlarged by adding, (1) standards for use in water analysis, (2) forms and tables of value in water purification work, and (3) drinking water standards of the Treasury Department for drinking and culinary water supplied by common carriers in interstate commerce.

To a great extent the spirit and characteristic wording of the original text have been retained. The book is not intended for the research worker or graduate student but rather for the undergraduate who is being introduced to the subject for the first time. Apparently for this reason considerable space is devoted to the citation of experiences and definite illustrations which provide an educational background for the student. This tends to create a more intense interest in the analytical procedures described.

As frequently happens in first printings, an occasional error appears: for instance, the term "chlorine" when chloride is intended has been correctly changed to chloride in the text—a corresponding change was not made in graphs; on page 150 the specification for the sterilization of glassware is given as 170° C. for 1½ hours, while an illustration on the facing page suggests 170° C. for 1 hour; and the page heading of eosin methylene blue agar is carried from pages 151 to 161 although it applies only to one page.

C. T. BUTTERFIELD

*A Short History of Nursing—By Lavinia N. Dock and Isabel Maitland Stewart (3d ed.). New York: Putnam, 1931. 404 pp. Price, \$3.00.*

Probably there are few graduate nurses today who did not study either

Nutting and Dock's large *History of Nursing*, or Dock and Stewart's *Short History of Nursing* while in nursing school. Both are classics in the nursing world. The *Short History of Nursing* has been completely revised. In it the newer trends in the nursing school curriculum and the changing points of view in the teaching of history are considered. The volume is written primarily for the use of students in the nursing schools of the United States and Canada and is designed as an introduction to the social and professional aspects of nursing. It is hoped that it will have an ever-increasing use among students of general history in high schools and colleges, as there is probably no more dramatic or moving story anywhere of the life saving adventures of the race than can be found in the long line of nursing pioneers who shared in many of the episodes of world history and who led in some of its most constructive movements.

The backgrounds and foregrounds of nursing have been painted with a broad sweep, and only enough dates and names have been left in to trace the sequence of events. The main emphasis has been placed on influences, issues and trends in nursing, and, after all, this is what most of us wish to get when we read history. It is very satisfying also to have all sentiment laid aside and these influences, issues, and trends, interpreted clearly, sanely, and without bias.

The first part of the book is essentially the same as in the older editions, but the last chapters, in which the authors show how modern nursing came to other countries, and describe the movement for self-organization, the widening field of nursing service and, finally, the future nurse, her heritage and trust, is all either new or old material which is interpreted in such a new and refreshing way that we nurses who have been living and working contemporaneously with these changes and trends

find a great deal of new information and feel a new thrill of accomplishment in reading them.

At the end of each chapter is a list of suggested reading so that one may delve more deeply into the history of nursing if she wishes—indeed she is encouraged to do so. In the appendices there is a fine list of reference books for teachers and students, and other valuable material pertinent to nursing is included. There is a good glossary and index. The ingenious maps and original drawings by Jessie H. Stewart delightfully and effectively assist in interpreting and reinforcing the text. This is by far the best short history of nursing on the market and can be recommended without qualification.

EVA F. MACDOUGALL

**Nutrition and Food Chemistry**—By *Barnard S. Bronson*. Wiley, 1930. 467 pp. Price, \$3.75.

The modern teacher of nutrition finds some difficulty in the selection of a text or texts for his students. He needs a descriptive text which will deal adequately with the chemistry of the foods and the chemistry of their digestion and assimilation. He needs an adequate treatment of the vitamins and their rôle in nutrition. He needs further a text which will discuss the nature of current food offerings, how they are made and how their manufacture affects their nutritive value.

His students on the other hand find the problem of maintaining a library of texts to cover this range of subjects somewhat of a financial burden.

Both teacher and student will find in Bronson's *Nutrition and Food Chemistry* a happy solution of their mutual problem in one volume. Dr. Bronson has happily combined the above features in his new text. He has made excellent selection of essentials in all the fields and expressed them in a language that is simple and clear. He has

not condensed or abbreviated where detail of exposition is necessary, but he shows a full appreciation of what is essential. I find his text one that it is a pleasure to recommend to any student of nutrition regardless of whether his interest is in the scientific or the applied phases of the subject.

WALTER H. EDDY

**Ohio Conference on Sewage Treatment, Fourth Annual Report, Dayton, Ohio, October 16-17, 1930.**

The fourth annual conference on sewage treatment was held at Dayton, O., October 16-17, 1930, and drew an attendance of 104.

Papers presented were on the Dayton sewage treatment plant, by M. W. Tatlock, a detailed description of the pumping equipment, mechanical treatment devices, operation and gas collection and utilization; experiences with industrial wastes at the Fostoria sewage treatment plant, by A. B. Cameron, a very long and complete paper describing the sewage treatment plant, the operation, the wastes present in the sewage, including amorphous carbon, oil and grease, ferrous sulphate and sulphuric acid, remedial measures employed, rehabilitation and improvement of the plant; discussion of problems in other Ohio cities caused by presence of industrial wastes in their sewage; Some Observed Effects of Dilution in the Self-Purification of Streams, by J. K. Hoskins, covering results of observations made by the Stream Pollution Investigations Station, U. S. Public Health Service, Cincinnati, on the Ohio River and tributaries, the Illinois River, and others; Relation between Design and Operation of Sewage Treatment Works, by Robert A. Allton; and Some Observations on the Design and Operation of Sewage Treatment Plants for Country Clubs and Private Estates, by R. F. MacDonald.

VINCENT B. LAMOUREUX

**Simple Lessons in Human Anatomy**  
—By B. C. H. Harvey, M.D. Chicago: American Medical Association, 1931. 434 pp. Price, \$2.00.

This is the publication in book form of a series of articles which appeared originally in *Hygeia*, the magazine published by the American Medical Association. There has been some revision, largely by the introduction of additional material and illustrations.

The book is divided into 20 chapters covering, in simple words, the anatomy, construction, and relationship of the various parts of the organs of the body. The material is written in a clear and interesting way, and is made even more interesting by the insertion, wherever it seems necessary, of some material on embryology, showing how the various structures originated and also some material on the hygiene of certain parts. There is a very interesting chapter discussing briefly the structure and function of the endocrine glands. The final chapter is on cell division.

Numerous clear and instructive illustrations greatly increase the value of the book.

The book was designed and written for the use of the layman. For him it is very valuable and interesting material. It enables him to get a fairly definite concept of the growth and structure of the human body in a relatively short time.

CHARLES H. KEENE

**Living the Liver Diet**—By Elmer A. Miner, M.D., with Introduction by William P. Murphy, M.D. St. Louis: Mosby, 1931. 106 pp. Price, \$1.50.

This book is prepared for the guidance of pernicious anemia patients. In the foreword the author states that he has written it from the viewpoint of both physician and patient. It is a handbook on the liver diet, and presents in detail its preparation and service. The 12 chapters are: the liver diet out-

lined, liver, fruits, meats, vegetables, fats, sweets, starches, milk, seasoning, drinks, and the diet maintained. The directions will serve for those with little knowledge of food to follow implicitly the Minot-Murphy diet.

Numerous directions are given for the preparation of liver so as to increase its palatability, and for the preparation and serving of the different foods discussed in the several chapters. The book will be extremely useful to those who must follow the dietary regimen imposed by the pernicious anemia patient.

E. V. MCCOLLUM

**Allergy—A Handbook for the Physician and Patient, on Asthma, Hay Fever, Urticaria, Eczema, Migraine, and Kindred Manifestations of Allergy**—By Warren T. Vaughan, M.D. St. Louis: Mosby, 1931. 359 pp. Price, \$4.50.

Dr. Vaughan has given us a comprehensive handbook on allergy in its protean aspects, based upon his own experience and a careful sifting of the literature on this intriguing subject.

The book first describes what allergy means and how it affects the individual. The chapter on Allergic Equilibrium is especially enlightening and gives one a clear picture of the interaction of specific and nonspecific factors in the production of allergic symptoms.

Part II presents a complete list of allergens and antigens with the botanical and common names of pollinating plants. The chapter on geographical locations of the most important plants causing hay fever is well illustrated and proves very helpful in locating offending pollens.

A discussion of practical methods of diagnosis follows. A detailed questionnaire for inhalant allergies aids in differentiating an allergic from a non-allergic illness. The part dealing with therapy will be read with profit by physician and patient alike. Food avoid-

ances, food groups, elimination diets, physiologic readjustments, vaccine therapy, etc., are all discussed thoroughly.

Part V deals with prognosis and Part VI gives the manifestations of allergy and describes in detail the symptoms which may be associated with it.

The book concludes with a consideration of applied immunology, and an extensive bibliography.

This book can be heartily recommended as a practical, concise, and authoritative statement on allergy and its manifestations. RICHARD A. BOLT

**Eye, Ear, Nose and Throat Manual for Nurses.** (2d ed.) By Roy H. Parkinson, M.D. St. Louis: Mosby. 223 pp. Price \$2.25.

Dr. Parkinson's manual has the virtues of simplicity, clarity, and brevity. The book is divided in three parts. The first, constituting nearly two-thirds of the total, is the outgrowth of a series of lectures given in a training school for nurses. The treatment is moderately uniform. Chapters I, II and III, devoted to the throat, nose and ear respectively, give anatomy and physiology of the organ considered, followed by common diseases and treatment, and a few suggestions on nursing care. The general rules for post-operative care of tonsil cases are so well given as to make helpful reading for the young nurse so often assigned to the nose and throat service before she has had her class work on the subject.

Chapters IV-VII deal with the eye in such detail as to convince the reader that this is the writer's field of major interest. In Chapter VII there are photographs illustrating procedures described, a method so effective that one regrets that it is used but twice in the textbook. Chapter VIII is a miscellany of suggestions chiefly on nursing care which might well have been distributed among the preceding chapters at the points of logical relation.

Part II, *Operating Room Technic*, could be used in part in teaching or as reference reading for student nurses preceding service in the operating rooms. The lists of instruments for each operation and the labelled photographs would prevent much of the confusion and discouragement frequently afflicting the student in her first days of duty. This section could have been improved by a brief statement of the steps in each operation. Too often the nurse has only a vague idea of what the surgeon is doing and her efficiency suffers thereby.

Part III is planned "to be an aid to the school nurse as well as to the district nurse in solving eye, ear, nose and throat problems which come to them." While it contains many good suggestions it is scarcely adequate for this purpose, though well adapted to the needs of a student nurse in her public health nursing class.

The manual is easy to read, the paper and type are well selected, and the style is simple. There are faults in diction and the indexing is incomplete. The questions appended to each chapter might help the student test her own understanding, but are not of the type used by teachers trained in present-day educational methods. There are no references.

The reviewer would recommend the book for reference in the library of any school of nursing. The advisability of adopting it for a given school could only be determined by comparison of the texts available, and consideration of other factors peculiar to the individual situation.

HAZELLE BAIRD DOUGLAS

**Social Work Year Book**—By Fred S. Hall and Mabel B. Ellis. New York: Russell Sage Foundation, 1930. \$4.00.

The Russell Sage Foundation has undertaken the biennial publication of

a book which gives the progress of social work. This book is not intended to be an encyclopedia of social problems or social conditions. It does, however, outline in logical sequence the advance which has been made during the current year in the field of social service and public health, and frequently overlaps into the closely related professions of education and medicine.

This, the first volume of the series, outlines a background in which is presented historically the steps which have led up to the present status. The book has been prepared by special contributors who have worked under a supervisory committee. An attempt has been made to record recent events and developments including: first, laws passed on topics included in the volume; and secondly, reports collected by the leading social service organizations, community chests, welfare, health, and education divisions of the government.

There have been supplied over 400 laws and 2,300 reports collected on schedules covering 63 different fields of social work. The book contains also a valuable reference to all the national health and social agencies including the purpose and activities of each and the number who constitute its membership.

HENRY F. VAUGHAN

#### Occupational Disease Legislation.

*Report of Committee on Standard Practices in the Problem of Compensation of Occupational Diseases, of the Industrial Hygiene Section, American Public Health Association—By Henry H. Kessler, Chairman. New York: A. P. H. A., 1931. 124 pp. Price, \$1.50.*

This report represents material which has been gathered since 1927 and condensed and revised to the current period. Both national and international authorities are agreed that occupational diseases should be compensated on the same basis as industrial accidents. The

arbitration of claims, however, is much more difficult to settle, because diseases do not lend themselves so readily to interpretation and indemnification as accidental injuries. A proposal for legislative action concerning this situation should have for its basis the background of experience.

Beginning with a brief history of the extension of workmen's compensation laws to occupational diseases, the laws of some 15 European countries, Mexico, Central, and South America, and those of the British Empire are covered, often in tabular form. Then follow those of the Canadian Provinces, 7 of 9 of which have an enumerated list of compensable occupational diseases as well as state insurance funds. Compensation boards administer them.

For the United States, the provisions of workmen's compensation acts are quite completely discussed. These are of two kinds: The all-inclusive or "blanket" coverage law adopted by California, Connecticut, The District of Columbia, Hawaii, The Philippine Islands, Massachusetts, North Dakota, Wisconsin, and United States civil employees as well as longshoremen and harbor workers; and the specific schedule or list of diseases recognized as compensable, and adopted by Illinois, Minnesota, New Jersey, New York, Ohio, and Porto Rico.

A final section is devoted to annual reports of cases and costs in the various states and insular possessions of the United States. There is also a brief section on diseases resulting from, or aggravated by, accidental injuries, another upon medical and surgical care of injuries, and one upon the reporting of occupational diseases. A list of references and a very complete index follow.

This very timely compilation of occupational disease legislation and its results throughout the world should appeal especially to legislative and social agencies, employers, insurance com-

panies and labor organizations, and to all who are interested in improving or changing existing legislation to conform with modern progress and standards.

Much credit is due Eleanor Rantoul, a member of the committee, who gathered the original data and revised it in its present form.

EMERY R. HAYHURST

**Fundamentals of Health**—By T. Bruce Kirkpatrick and Alfred F. Huettner. New York: Ginn, 1931. 576 pp. Price, \$3.80.

This is a textbook of hygiene intended to stimulate the interest and stir the imagination of college students by including subjects such as the genesis of life, phenomena of reproduction, growth and development, endocrinology and immunology. Each chapter is thorough in the treatment of its subject matter, with clear illustrations and a list of references appended for further reading.

Chapter I deals with the evolution of man, tracing the Crô-Magnon type upwards to *Homo sapiens*. At the end of this chapter the aim of the book is stated as indicating how the human body may adapt itself to an ever changing environment by judicious habits of living.

Chapters IV and V present an excellent account, condensed yet exhaustive, of foods and nutrition. In Chapters VI, VII, VIII and IX the anatomy and physiology of the muscular, circulatory, respiratory, and excretory human systems are outlined with practical examples of preventing common disorders of these systems.

An account of the nervous system is given in Chapters X and XI with a discussion of its adjustments and interrelationships with the internal secretions.

The book closes with a chapter on the public health, in which some of the tables require revision, e.g., the infective organism of typhus fever is wrongly stated in Table XXVIII but correctly in Table XXX and *Leptospira icteroides* is erroneously stated as the causative organism of yellow fever.

Sundwall (*Am. J. Pub. Health*, Jan., 1927) has emphasized that the subjects in a college course of hygiene should embrace a study of the factors governing health promotion and disease prevention and control. In *Fundamentals of Health* the authors have presented a concise account of the factors included in both these groups. A careful perusal of this splendid textbook will interest the student in personal and community hygiene.

JOHN WYLLIE

## BOOKS RECEIVED

**MENTAL HEALERS.** By Stefan Zweig. New York: Viking Press, 1932. 363 pp. Price, \$3.50.

**PSYCHOLOGY AND PSYCHIATRY IN PEDIATRICS.** The Problem. Report of the Subcommittee on Child Health and Protection. New York: Century Co., 1932. 146 pp. Price, \$1.50.

**BODY MECHANICS: EDUCATION AND PRACTICE.** White House Conference on Child Health and Protection. New York: Century Co., 1932. 166 pp. Price, \$1.50.

**SOCIAL PROBLEMS AND SOCIAL PLANNING.** The Guidance of Social Change. By Cecil Clare North. New York: McGraw-Hill, 1932. 409 pp. Price, \$3.50.

**MEDICAL SUPERVISION AND SERVICE IN IN-**

**DUSTRY.** National Industrial Conference Board, 1932. 125 pp. Price, \$2.00.

**EXERCISE AND PHYSIOLOGY.** By A. C. Gould and Joseph A. Dye. New York: Barnes, 1932. 434 pp. Price, \$3.00.

**CANCER. WHAT EVERYONE SHOULD KNOW ABOUT IT.** By James A. Tobey. New York: Knopf, 1932. 313 pp. Price, \$3.00.

**THE CONTROL OF TUBERCULOSIS IN THE UNITED STATES.** By Philip P. Jacobs. New York: National Tuberculosis Association, 1932. 407 pp. Price, \$2.00.

**THE STORY OF MEDICINE.** From Medicine Man to Modern Physician. By Victor Robinson, 1931. 527 pp. Price, \$5.00.

**FEEDING A FAMILY AT LOW COST.** Chicago: Evaporated Milk Association, 1932. 15 pp.

# A SELECTED PUBLIC HEALTH BIBLIOGRAPHY WITH ANNOTATIONS

**Hourly Nursing**—A brief account of an hourly appointment nursing demonstration in Chicago, a project of the Rosenwald Fund and a service with great possibilities.

AMES, M. Organized Hourly Nursing in Chicago. *Pub Health Nurs*, 34, 1: 17 (Jan.), 1932.

**Detroit's Diphtheria Study**—Not to be missed is this excellent account of the epidemiologic study made of recent diphtheria cases in Detroit. The paper is too good to be spoiled by a partial summary here.

ANON. Diphtheria Studies in Detroit. *City Health* (Detroit Department of Health), 15, 4: 4 (Nov.-Dec.), 1931.

**Diphtheria Immunization Results**—In Philadelphia, 55 per cent of the preschool children and more of the school population have been immunized against diphtheria, the incidence of which has been reduced 80 per cent. Of the cases occurring, 99.3 per cent are among unimmunized children. Bacteriologically, the disease is as virulent as ever.

BAUER, E. L. A Survey of Diphtheria Prevention in Philadelphia. *Am. J. M. Sc.*, 182, 6: 839 (Dec.), 1931.

**Medical Graduates and Hygiene**—Brief but illuminating comment on what candidates for medical licenses did with twelve questions on hygiene. None answered correctly the question: What is the sanitary code and by whom enacted?

BROOKS, P. B. Results of a Recent Hygiene Examination. *New York State J. Med.*, 32, 2: 70 (Jan. 15), 1932.

**More "Colds" Prophylaxis**—The results of this experiment in the prevention of colds with vaccine show little

if any improvement in the treated group compared with the control.

BROWN, W. E. Vaccine in the Prevention of the Common Cold: An Experiment. *Am. J. Hyg.*, 40, 1: 36 (Jan.), 1932.

**Whooping Cough Epidemiology**—Intensive observation of whooping cough cases as they developed in a rural group constituted an excellent opportunity to study attack rates among contacts.

BURROUGHS, T. P. An Epidemiological Study of a Rural Outbreak of Whooping Cough. *Quart. Bull. (Millbank Memorial Fund)*, 10, 1: 41 (Jan.), 1932.

**Typhoid Fever**—Typhoid carriers are still with us and will be for another quarter century. In the meantime, safeguards cannot be lowered and higher standards of personal hygiene must be maintained. A timely warning.

CUMMING, J. G. Should the Barriers Against Typhoid Be Continued? *J. A. M. A.*, 98, 2: 93 (Jan. 9), 1932.

**Hydrocyanic Acid**—This brief discussion of the cutaneous absorption of hydrocyanic acid gas will be valuable to those who have to use this fumigant.

DRINKER, P. Hydrocyanic Acid Gas Poisoning by Absorption through the Skin. *J. Indust. Hyg.*, 14, 1: 1 (Jan.), 1932.

**Pasteurization in Canada**—A Canadian symposium on pasteurization indicating that the Dominion sanitarians think with us, and not with the views on the subject expressed in journals published in England.

HARRIS, R. I., *et al.* The Menace of Raw Milk. *Canad. Pub. Health J.*, 23, 1: 1 (Jan.), 1932.

**Chlorine in Sewage**—The practical uses of chlorine in disinfecting sewage, controlling odors, overcoming

other plant operation difficulties, and conditioning sludge are discussed.

GOUDY, R. F. The Increased Use of Chlorine in Sewage Treatment. *Municipal Sanitation*, 3, 1: 10 (Jan.), 1932.

**Smoke and Cancer**—As a "horrible" example of fallacious juggling of crude statistics, this paper and its attendant discussion should be read by all who are tempted by the desire to prove a pet theory statistically. Smoke causes cancer, believes the author. For proof, she adduces such an irrelevant idea as this: the British housewife who cleans the soot from the grate and chimney pays the toll in breast and uterine cancer.

MUDIE, E. C. Air Pollution and the Rising Tide of Cancer. *J. Roy. San. Inst.*, 52, 7: 292 (Jan.), 1932.

**More Diphtheria Immunization**—British experience is reported in which none of the immunized children is known to have contracted typical diphtheria.

NASH, E. H. T., and BOUSFIELD, G. An Immunization Campaign and Its Results. *Med. Off.*, 47, 3: 25 (Jan. 16), 1932.

**School Health Administration**—Very practical is this discussion of the set-up and objectives of the school child health program, pointing out the many hurdles in the path to successful administration.

PERRIN, E. A Health Issue in the School Today. *J. Health & Physical Ed.*, 3, 1: 15 (Jan.), 1932.

**More Maternal Mortality**—Another worth while contribution to the discussion about the accuracy of maternal

death rates which suggests that the conditions are not as bad as the unanalyzed statistics would indicate.

RICHARDSON, B. K. Maternal Mortality. *Illinois Health Quart.*, 3, 4: 258 (Oct.-Dec.), 1931.

**Dental Defects and Sex**—More boys among the younger children and girls among the older ones had decayed, missing or filled teeth. A very much greater percentage of boys than girls had marked decay and more girls than boys had filled teeth.

STOUGHTON, A. L., and MEAKER, V. T. Sex Differences in the Prevalence of Dental Caries. *Pub. Health Rep.*, 46, 1: 26 (Jan. 1), 1932.

**Fertility Rates**—This study of the fertility rates of native white women in a rural area suggests evidence of unchanging fertility of native stock under a not greatly changing environment. Every health worker should see this bulletin if only for its exquisite format. He will return to his own publications to "read 'em and weep."

SYDENSTRICKER, E. A Study of the Fertility of Native White Women in a Rural Area of Western New York. *Quart. Bull. (Millbank Memorial Fund)*, 10, 1: 17 (Jan.), 1932.

**Cold Feet**—The concluding sentence of the summary of an important contribution to our knowledge of physiologic response to air temperatures reads: "So far as the work here reported may be significant, however, it does not confirm the general belief that chilling of the feet is specially harmful."

WINSLOW, C.-E. A., and GREENBURG, L. Vasomotor Reactions to Localized Drafts. *Am. J. Hyg.*, 15, 1: 1 (Jan.), 1932.

## NEWS FROM THE FIELD

### CANADIAN PUBLIC HEALTH MEETING TO BE IN TORONTO

THE Twenty-First Annual Meeting of The Canadian Public Health Association will be held in Toronto, May 25 to 27. The meeting will be held in conjunction with the Sixteenth Annual Meeting of the Ontario Health Officers Association.

### FIGHTING INFANT MORTALITY IN BOMBAY

THE commissioner of public health for all India reports that in 1928 the infant mortality rate in Bombay was 290 per 1,000 live births, according to the London magazine *Mother and Child*. To combat this serious condition and the high maternal mortality the maternity department of the Bombay municipality is maintaining 5 free municipal maternity homes in different sections of the city. The department also maintains milk stations at which milk is distributed free or at a nominal price. Plans are also being made to establish dairies in the suburbs to assure the city a purer milk supply. Most of the present supply is produced within the city limits.

The Bombay Infant Welfare Society includes in its activities 2 maternity homes, a crèche for children of industrial workers, and 8 infant welfare centers. These 8 centers also distribute milk at a nominal price. The government of the Bombay Presidency has established in the city three hospitals which have prenatal and postnatal clinics.

A month's leave on full average pay, both before and after childbirth, is granted to women factory workers by the Bombay Maternity Benefit Act. A

woman physician with the status of factory inspector looks after their interests. The draft of a bill which would compel the registration and supervision of midwives and provide for the appointment of a woman physician to administer the law as assistant to the health officer has been forwarded to the government by the Medical Women's Association of Bombay.—U. S. Children's Bureau, Washington, D. C.

### WESTERN BRANCH CHANGES MEETING DATE

THE Third Annual Meeting of the Western Branch of the American Public Health Association is now definitely fixed for June 9-11, in Denver, Colo.

### COST OF MEDICAL CARE

DR. BENJAMIN C. GRUENBERG, of New York, has accepted a temporary appointment to the staff of the Committee on the Costs of Medical Care.

Dr. Gruenberg has been granted a leave of absence by the Viking Press, New York, to take up his post with the committee. He has been educational editor of this publishing firm since 1929, prior to which time he was managing director of the American Association for Medical Progress.

The committee has completed practically all the preliminary research in its exhaustive 5-year study into the problem of "the delivery of adequate, scientific medical service to all the people, rich and poor, at a cost that can be reasonably met by them in their respective stations in life." Its final report will be published in the autumn of 1932.

NEW JERSEY HEALTH DEPARTMENT  
NEWS

NEW employees added to the staff of the New Jersey State Department of Health recently included: two district health officers, D. C. Bowen and Clyde R. Newell, of Freehold; three assistant sanitary engineers, Leigh W. Morrill, of Collingswood, Donald M. Ditmars, of Trenton, and Robert S. Shaw, of Lawrence Township; and two water shed inspectors, John H. Crabel, of Pennington, and Lewis W. Klockner, Jr., of Bloomsbury.

## FOOD RELIEF FOLDER

A FOLDER on emergency food relief and child health has been issued jointly by the U. S. Children's Bureau and the U. S. Bureau of Home

Economics, for the use of social agencies throughout the United States whose work it is to provide the food necessary to safeguard the health and growth of the children of the families in their charge. The importance of the adequate diet is emphasized in this folder, and much attention is given to what is stated to be the "irreducible amounts" of foods below which it is not safe to let the diet fall, even for short periods of time, with lists of minimum weekly quantities.

## NATIONAL NEGRO HEALTH WEEK

THE U. S. Public Health Service has issued a preliminary announcement on the Eighteenth Annual Observance of National Negro Health Week, April 3 to April 10, 1932.

## PERSONALS

DR. HENRY S. WELLCOME, of London and Washington, was knighted by King George and had his name included in the New Year's Honours List. Dr. Wellcome is now serving as Honorary President of the American Pharmaceutical Association.

DR. JAY ARTHUR MEYERS, member A. P. H. A., has recently been promoted from associate professor to professor of preventive medicine at the University of Minnesota School of Medicine, Minneapolis.

DR. VINTON A. SELBY, member A. P. H. A., of Clarksburg, W. Va., resigned recently as Health Officer of

Harrison County and was succeeded by Dr. Americus J. Kemper, of Lost Creek, W. Va.

DR. LINCOLN A. SUKEFORTH, member A. P. H. A., for 8 years Director of Public Health of Duluth, Minn., has retired.

DR. O. T. AVERY of the Rockefeller Institute, member A. P. H. A., has been selected to receive the first John Phillips Memorial Prize for 1932, which will be presented to him at the Sixteenth Annual Clinical Session of the American College of Physicians in San Francisco during the week of April 4, 1932.

## CONFERENCES

March 6-9, International Congress and International Exhibit of Sanitary Technique and Urban Hygiene, Lyons, France.

April 4-8, American College of Physicians, San Francisco, Calif.

April 11-15, American Nurses Association, San Antonio, Tex.

April 11-15, National Organization for Public Health Nursing, San Antonio, Tex.  
April 11-15, National League of Nursing Education, San Antonio, Tex.  
April 19-23, 37th Annual Convention of the American Physical Education Association, Philadelphia, Pa.  
May 9-10, American Association of Medical Milk Commissions, and the Certified Milk Producers' Association of America, New Orleans, La.  
May 10-15, Annual Congress of The Royal Institute of Public Health, Belfast, Ireland.  
May 15-21, National Conference of Social Work, Philadelphia, Pa.  
May 25-27, The Canadian Public Health Association, 21st Annual Meeting, in association with Ontario Health Officers' Association, Toronto, Ont.  
June 6-9, National Tuberculosis Association, Colorado Springs, Colo.

June 9-11, Third Annual Meeting, Western Branch, American Public Health Association, Denver, Colo.  
July 21-29, 1932, 100th Anniversary Meeting, British Medical Association, London.  
July, 1932, The Second International Conference of Social Work, Frankfurt.  
August 15-18, International Congress for Light, Copenhagen.

MEDICAL BIOLOGY COURSE  
Four year course leading to  
B.S. degree

Well equipped laboratories of the College, the Michigan State Department of Health and large city hospitals are available. Prepares for laboratory positions in chemistry, serology, bacteriology and pathology.  
Catalog sent on request. Address Professor of Bacteriology and Hygiene, Michigan State College, East Lansing, Michigan.  
**Course in Veterinary Medicine**  
Full four year college course leading to degree D.V.M. For information, address Dean of Veterinary Medicine, Michigan State College, East Lansing, Michigan.

*Application for Membership*

I wish to apply for membership in the American Public Health Association.

Name .....  
Print name in full and give degree

Street and City ..... State .....  
For correspondence and the Journal

Present public health occupation .....

**MEMBERS:** Persons professionally engaged in public health work from the United States, Canada, Mexico, and Cuba are eligible for election as Active Members. Persons interested in public health, from any country, are eligible for election as Associate Members.

**DUES:** Dues of Members of either class are \$5.00 per year, which includes an annual subscription to the American Journal of Public Health.

### Ice Cream Sanitation and Control<sup>\*</sup>

F. W. FABIAN, PH. D., F. A. P. H. A.

*Department of Bacteriology and Hygiene, Michigan State College,  
East Lansing, Mich.*

DURING the past two years the ice cream industry has made rapid advances in sanitation and control. In this paper I shall attempt briefly to outline the most important of these.

Two significant changes have been made in the field of sanitation. The first is the reduction of the aging period of the ice cream mix from 24 hours and longer to 2-4 hours. It has been shown by several investigators that the longer aging period is unnecessary to produce the desired overrun, and the product is equal in every respect to that aged for 24 hours or longer. Since there is an increase in the bacterial content during the aging period, this decrease in time naturally lowers the count, other things being equal.

It has been recently discovered that the ice cream mix may be pasteurized at temperatures as high as 170° F. without materially affecting the flavor, texture, and body of the finished product. Temperatures up to 170° F. actually improve the whipping quality of the mix. One can readily appreciate the significance from a sanitary standpoint of increasing the pasteurizing temperature of such a viscous product. The higher temperature will materially reduce the bacterial content and greatly reduce the chances of pathogenic bacteria surviving. Pasteurizing temperatures of 140°-145° F. are common in the milk industry and have been almost universally accepted by the ice cream makers without any consideration as to the difference between the two products. There is no question that the minimum pasteurizing temperature for ice cream should be 150° F. for 30 minutes, while the maximum may be as high as 170° F. for 30 minutes.

---

<sup>\*</sup> Read at a Joint Session of the Public Health Engineering and Food, Drugs and Nutrition Sections of the American Public Health Association at the Sixtieth Annual Meeting at Montreal, Canada, September 16, 1931.

Other improvements in sanitation are the introduction of "dry ice," which enables retailers to distribute the product in an economic and sanitary manner, and the introduction of supplementary chemical sterilization—an important factor in reducing contamination from machinery, which may be an important source of bacteria in ice cream unless controlled.

The past year has seen considerable activity concerning ice cream legislation. There were 66 bills introduced in 37 states affecting the manufacture and sale of ice cream, exclusive of the general state revenue bills. Consideration of these will be confined to their bacteriological aspect.

California, in 1927, enacted a law establishing a maximum legal bacterial standard of 150,000 bacteria per gm. for ice cream. Three other states have taken similar steps during the past year. Connecticut has a maximum bacterial standard of 100,000 per c.c., Michigan 150,000, and Iowa 250,000 (packaged goods). Two other states had bills establishing bacterial standards before their legislatures (Minnesota 250,000 per c.c. and Nebraska 150,000 per c.c.), but they failed to pass. Connecticut and Michigan passed laws requiring ice cream mix to be pasteurized.

It is fairly safe to predict that during the next few years a majority of the states will enact laws establishing a maximum bacterial standard and greatly increase their existing sanitary requirements.

#### NUMBER OF BACTERIA IN ICE CREAM

There should no longer be any question about the ability of manufacturers to produce ice cream with a low bacterial content. Four sets of figures from 3 widely separated states and 1 province are presented for your consideration. Those presented in Table I were compiled through the courtesy of Frank E. Mott, Milk Inspector and Chemist of the Boston Board of Health.

Note the gradual improvement during 1926 and 1927, the sudden improvement for 1928 over the 2 previous years, and the high standards for 1929 and 1930. The great improvement in 1928 and subsequent years was due for the most part to regulations put in force September, 1928, and also to the establishment of a permit system, discussed later.

When California established a legal standard of 150,000 bacteria per gm., a complete survey of the state showed that only 55 per cent of the ice cream samples met the legal standards. The following data compiled by M. E. McDonald, Chief of the Bureau of Dairy Control of the California Department of Agriculture, show the progress made since then.

TABLE I

RESULTS OF BACTERIOLOGICAL EXAMINATION OF ICE CREAM IN BOSTON, MASS., OVER A 5-YEAR PERIOD

Total Samples Examined	Year				
	1926	1927	1928	1929	1930
	996	940	837	775	440
Colonies of Bacteria per c.c.	Per cent of Samples Examined				
Under 50,000	4.9	0.8	0.6	51.8	76.6
50,001 to 100,000	9.6	12.7	20.0	35.4	11.1
100,001 to 200,000	36.4	45.6	57.0	7.8	4.4
Total under 200,000	50.9	59.1	77.6	95.0	92.1
200,001 to 300,000	13.6	16.0	13.0	1.1	2.6
300,001 to 400,000	8.3	10.0	4.2	0.2	0.4
400,001 to 500,000	5.6	5.2	1.8	0.3	0.8
500,001 to 600,000	2.1	1.5	0.5	0.9	0.8
600,001 to 1,000,000	6.9	4.6	0.9	0.7	1.5
1,000,001 to 3,000,000	6.0	2.4	2.0	1.6	1.8
3,000,001 to 5,000,000	3.4	1.3	0.0	0.2	0.0
Above 5,000,000	3.2	0.0	0.0	0.0	0.0

	Per cent of Samples Legal
First survey, 1927-1928	55.0
Second survey, 1928	64.0
Total of all samples, 1929	70.0
Total of all samples, 1930	73.4
First 6 months of 1931	79.0

The above data are compiled on the basis of all samples from all factories in the state, including those making a million gallons annually, and those making only a few hundred gallons. Mr. McDonald states:

On a volume basis I feel safe in stating that 98 per cent of the ice cream manufactured in California is coming well within the limit of 150,000 bacteria per gm. . . . It is interesting to note that this improvement has been accomplished without the necessity of any legal action. The results of bacteria counts have in the past been used as a guide for detailed inspections rather than as a basis for prosecution. However, we feel that the manufacturers have had ample time to familiarize themselves with the necessary equipment and precautions essential to the manufacture of a quality product and we are using somewhat more drastic means of bringing about improvement.

In Table II are included detailed data from Los Angeles, Calif., compiled by William Veit, City Veterinarian and Director of Meat and

TABLE II

RESULTS OF BACTERIOLOGICAL ANALYSIS OF ICE CREAM OF LOS ANGELES, CALIF., DURING THE PAST YEAR

Colonies of Bacteria per c.c.	No. of Samples Examined	Per cent of Samples Examined
Up to 1000	143	19.2
1,001 to 10,000	336	45.2
10,001 to 50,000	146	19.6
50,001 to 100,000	38	5.0
Total under 100,000	663	89.0
100,001 to 200,000	26	3.5
200,001 to 300,000	14	1.9
300,001 to 400,000	10	1.4
400,001 to 500,000	5	0.7
500,001 to 1,000,000	10	1.4
1,000,001 to 5,000,000	15	2.1
Over 5,000,001	0	0.0
Total	743	100.0

Milk Inspection. They show the extremely low counts of much of the ice cream sold in that city.

Through the courtesy of Russell A. Palmer, Chief Milk Inspector for the Detroit Board of Health, the data in Table III were made

TABLE III

RESULTS OF BACTERIOLOGICAL EXAMINATIONS OF ICE CREAM IN DETROIT, MICH., DURING THE PAST SIX YEARS

Total Samples Examined	Year					
	1925	1926	1927	1928	1929	1930
	201	87	218	86	394	332
Colonies of Bacteria per c.c.	Per cent of Samples Examined					
Under 50,000	51.7	50.6	48.6	74.5	90.3	81.6
50,001 to 100,000	17.4	25.4	21.6	11.7	4.4	10.8
Total under 100,000	69.1	76.0	70.2	86.2	94.7	92.4
100,001 to 200,000	13.4	8.0	14.2	4.7	2.5	7.0
200,001 to 300,000	1.5	8.0	3.2	4.6	0.8	0.6
300,001 to 400,000	6.0	1.0	3.1	0.0	0.7	0.0
400,001 to 500,000	0.5	0.0	2.6	2.3	0.0	0.0
500,001 to 1,000,000	5.0	7.0	3.1	1.1	1.0	0.0
1,000,001 to 5,000,000	3.0	0.0	3.6	1.1	0.3	0.0
5,000,001 and over	1.5	0.0	0.0	0.0	0.0	0.0

available. They show the great improvement which has taken place during the past few years. Compare these with similar data secured by me in 1917, the first time an attempt was made to inspect the Detroit plants and analyze their product. At that time there were no samples that had less than 50,000 bacteria per c.c. and only one, or 0.86 per cent, below 100,000. Out of 116 samples, 64.66 per cent had 1,000,000 or more bacteria per c.c.

Table IV gives the results of bacterial analysis of 1,070 samples of ice cream during 19 months by the Toronto Board of Health, compiled by A. B. Moffat, Director of Laboratories of the Department of Public Health.

TABLE IV

RESULTS OF BACTERIOLOGICAL ANALYSIS OF ICE CREAM BY THE BOARD OF HEALTH, TORONTO, CANADA, JANUARY 1, 1930, TO AUGUST 26, 1931

Colonies of Bacteria per c.c.	No. of Samples Examined	Per cent of Samples Examined
50,000 to 100,000	820	76.6
100,001 to 200,000	120	11.2
200,001 to 300,000	28	2.6
300,001 to 400,000	37	2.8
400,001 to 500,000	12	1.1
500,001 to 1,000,000	34	3.1
1,000,001 to 5,000,000	15	1.4
5,000,001 and over	10	0.9
Total	1,070	100.0

#### WHAT IS A REASONABLE BACTERIAL STANDARD FOR ICE CREAM?

In view of the fact that legal bacterial standards in various cities of the United States range from 100,000 to 800,000, and in the 4 states which have legal standards from 100,000 to 250,000, per c.c. or per gm., as the case may be, it may be asked, what is a reasonable legal bacterial standard for ice cream? I would reply without any hesitation, 100,000 per gm. Some will consider this standard too rigid. They should be apprised of the fact that the health department of Shanghai, China, considers ice cream containing 100,000 bacteria or more per gm. as unfit for human consumption. However, the principal reasons for establishing this particular figure are:

1. A detailed study of one ice cream plant for 3 years which consistently (99.9 per cent of the samples) produced ice cream with a bacterial count of less than 100,000 during that period showed it was both possible and practical.
2. Experience with a large variety of plants shows that some produce ice cream with a low and some with a high bacterial content. To which class a plant belongs

depends entirely upon the sanitary practices employed. Almost without exception the samples showing high bacterial counts are from a few plants, in which the sanitary conditions are not what they should be.

3. There are great advances in ice cream manufacturing in both methods and equipment. Few industries have more elaborate equipment and machinery, designed in most cases with both utility and sanitation in mind. The influence of the improved methods will be reflected in the bacterial count. The most important of these are aging, pasteurizing, sterilizing and refrigerating. After it passes through the aging process ice cream is kept at or below the freezing point until consumed. While this may not destroy all types of bacteria, it certainly has a tendency to reduce the number of bacteria, and what is of equal importance, prevents the multiplication of most types.

When one considers that much of the milk produced and sold today in many cities comes well within the 100,000 bacterial limit, it is not hard to understand why this is a reasonable standard for ice cream.

Finally, additional data, not presented here, show that the bacterial counts for ice cream in other cities which have no bacterial standard or a very liberal one are far in excess of those in cities which have a very strict bacterial standard.

#### COLON GROUP AS AN INDEX OF SANITATION

There has been considerable discussion concerning the use of the colon group of bacteria as an index of the sanitary quality of ice cream. It is maintained by some that since this group are inhabitants of the intestinal tract their presence indicates fecal contamination and, therefore, potential danger.

The objections to the colon test are: (1) That it was designed primarily as an index of the sanitary quality of water where their number rather than their presence is used as the criterion; (2) that large numbers of colon organisms in ice cream or any other dairy product do not have the same sanitary significance as in water, since in milk and its products they tend to increase while in water they tend to decrease; (3) That there are 2 groups of closely associated bacteria, which may contaminate milk—the colon or fecal group found in the intestine, and the aerogenes or non-fecal group found in soil, grain, vegetable material, etc. The sanitary significance of the groups is entirely different; yet they are distinguished from each other only by special tests.

The consensus of opinion is that in order properly to interpret the colon test in ice cream or any dairy product, it is necessary to know the history of the sample; and further, it is not a reliable index of pasteurizing efficiency since there is considerable variation in the thermal death point of different strains and of the same strain at different times.

## SUGGESTIONS FOR SANITARY CONTROL

Experience has shown that there are several effective methods of control. The first is a law or ordinance. Some of the most important considerations of such a law or ordinance should be:

1. The type of raw materials which should be used.
2. It should not permit the reprocessing of ice cream mix.
3. It should define pasteurization—150° F. for 30 minutes to be the minimum.
4. A maximum bacterial standard should be stipulated—100,000 per gm. suggested as reasonable.
5. It should require a periodic medical examination of all those handling the product.
6. All plants manufacturing ice cream should be required to secure a license from the board of health, and, before such license is issued, be required to pass a rigid inspection. The license should be renewed yearly.
7. All those who sell ice cream should be required to obtain a permit from the board of health. Before the permit is issued, they should be required to pass an examination. The permit should be issued for a period of 1 year only.
8. There should be periodic inspection of all places manufacturing and selling ice cream. They should be inspected at least 4 times each year. The inspector should use a score card to evaluate each place. A copy of the score should be left with the person in charge with written instructions as to any alterations or criticisms.

## SUMMARY

The most significant changes from a sanitary standpoint are the reduction of the aging period from 24 hours or longer to 2 to 4 hours; the fact that ice cream may be pasteurized at temperatures as high as 170° F. for 30 minutes without affecting its quality, and the use of "dry ice" and chemical sterilization.

From the standpoint of control a few states are recognizing the value of bacterial standards for ice cream, 4 now having such standards. It is believed that a maximum bacterial standard of 100,000 bacteria per gm. is reasonable. Bacteriological data are given for 3 widely separate states and 1 province showing the progress being made in this direction.

Reasons for and against the colon test as an index of the sanitary quality of ice cream are given. It is generally agreed that it is necessary to know the complete history of the sample before the test can be of value.

Suggestions for the sanitary control of ice cream are given. They include the establishing of a law or ordinance defining the type of raw materials, pasteurization, and a bacterial standard. A license should be required for the manufacture of ice cream; a permit for its sale, and the periodic medical examination of those handling the product should also be required. Provision should be made for regular inspection of all establishments manufacturing and handling ice cream.

# Relative Pneumonia Fatality among Surface Workers and Miners\*

A Study of 2,603 Cases of Pneumonia and 238 Deaths from Tuberculosis in the Experience of the Tennessee Coal, Iron and Railroad Co., 1925 to 1930 Inclusive

C. H. KIBBEY, M. D., F. A. P. H. A.

*Director of Sanitation, Tennessee Coal, Iron and Railroad Co., Fairfield, Ala.*

THE inhalation of various forms of dust inherent in certain occupations and the possible relationship of dust deposit in the lungs to the frequency and fatality of pulmonary disease among certain classes of industrial workers has engaged the serious attention of industrial hygienists for many years.

Pneumonoconiosis has been recognized as a distinct pathological entity since the work of Ramazini (1703), who based his observations on the result of autopsies following death from, among other causes, miners' phthisis.

It has long been observed that pulmonary tuberculosis occurs with comparatively greater frequency in persons following some occupations than others. "Coal miners' phthisis" has been made the subject of much speculation as well as experimental study. Sir Thomas Oliver, one of Great Britain's leading industrial medical authorities, considers the terms "anthracosis" and "coal miners' phthisis" as synonymous, but quotes figures to show that coal miners do not die from tuberculosis with as great frequency as do "other occupied males."

In the United States "all other occupied males" (a somewhat comprehensive group which includes lawyers, physicians, carpenters, plumbers, etc.) exhibit a mortality rate from tuberculosis nearly 3 times as great as do coal miners.

The Illinois State Board of Health published (1927) figures which tended to show that coal miners in that state were the least liable

Pneumonia Case Incidence in Relation to Population Groups

to respiratory diseases and death of any wage earning group, following the figures with the statement: "Contrary to popular belief, working in coal mines does not predispose to tuberculosis, pneumonia, influenza and other respiratory diseases."

In 1924, we showed a U. S. Government representative through some of our coal mining operations. He asked: "To what extent do your miners have anthracosis?" and upon being told that practically 100 per cent of them had the condition to an extent capable of being demonstrated with the X-ray, he wanted to know what our relative pneumonia fatality was among coal miners as compared to other workers.

The embarrassment occasioned by this experience has resulted in the present study, which is in the nature of a preliminary review.

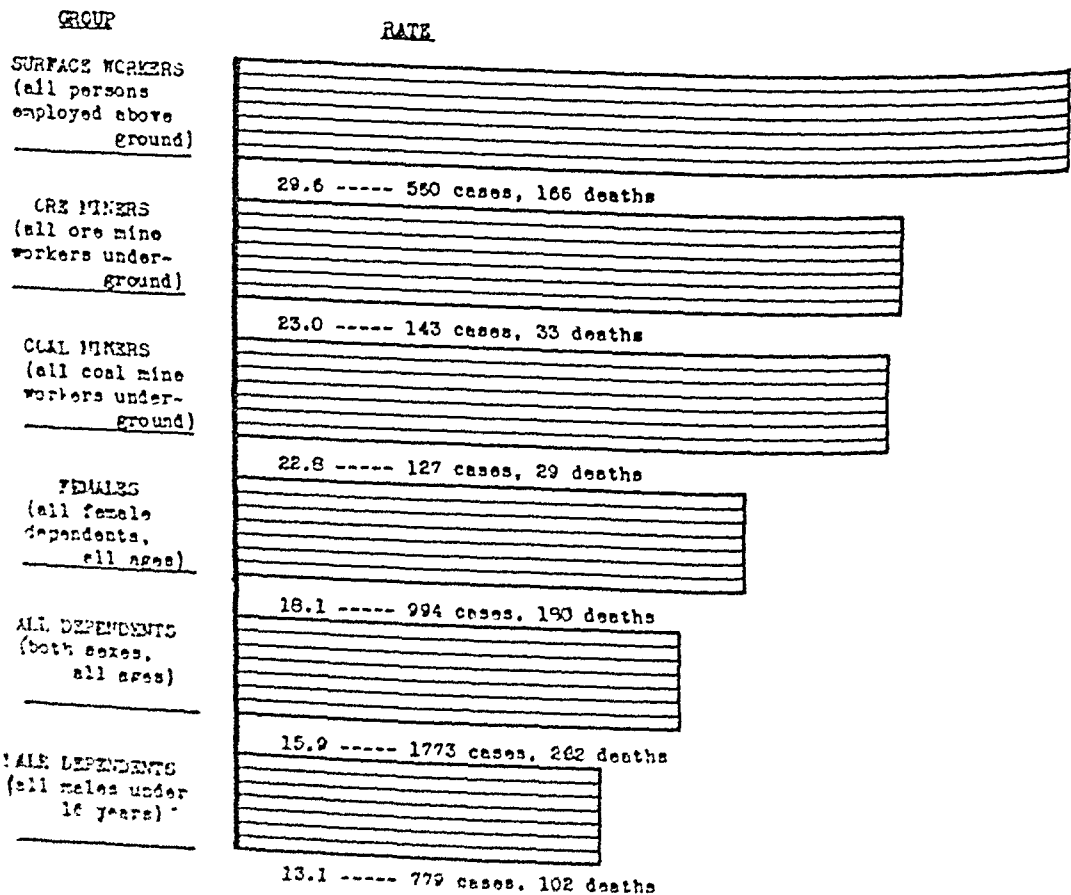

Our company operates several coal and red ore (hematite) mines;

employs more than 60 whole-time physicians; and maintains a 300-bed base hospital. Following the experience just mentioned, we began recording all cases of, and deaths from, pneumonia and tuberculosis. We have classified these according to age, sex, color and occupation, and present a tabulation comprising 2,603 cases of pneumonia, and 238 deaths from tuberculosis during 6 years, 1925 to 1930, inclusive.

For the purpose of this study all persons entitled to medical service have been divided into surface workers, coal miners, ore miners, female and male dependents. Each group has been again subdivided into white and colored.

The term "surface worker" applies to all employees, of whatever status, who work above ground, and includes clerks, accountants, superintendents, school teachers, nurses, and physicians. "Coal miners" will be understood to mean all coal mine employees who

CHART II  
TENNESSEE COAL, IRON AND RAILROAD COMPANY  
Health Department  
Pneumonia Fatality 1925-1930  
Occupational Groups  
(Rate in deaths per 100 cases)

work underground, including track men, motor men, safety men, mine foremen, etc. "Ore miners" is used to designate all ore mine employees whose duties keep them underground during the working shift. "Female dependents" means all unemployed females of all ages; "male dependents" all males 16 years of age and under.

Among the astonishing and apparently contradictory facts which our experience appears to disclose may be enumerated:

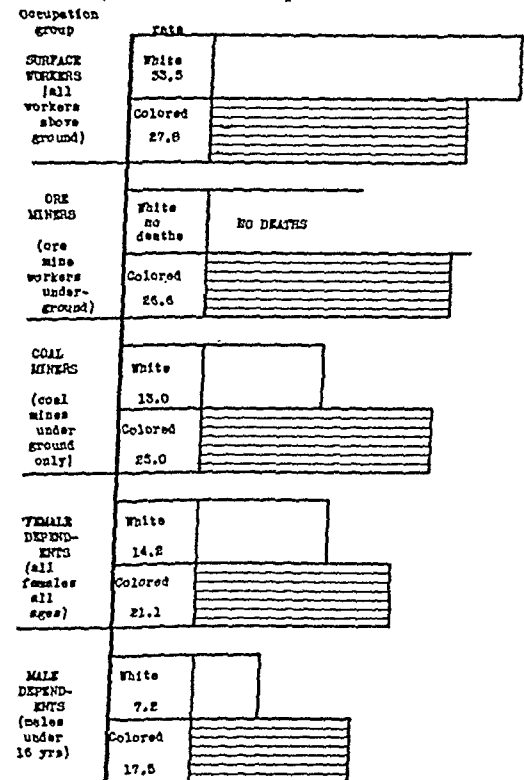

1. Our coal miners have a higher mortality rate from tuberculosis than any other wage earning group.
2. Of all wage earners those employed above ground have the lowest tuberculosis mortality rate.
3. The highest pneumonia case incidence rate is found among underground workers in the iron ore mines.
4. The lowest pneumonia case incidence rate and the highest fatality rate have occurred among surface workers.
5. No death has occurred from pneumonia during the 6 years in any white ore miner. (Only 19 cases have occurred in this group so that 1 more case might mean a 5 per cent fatality rate. The only other group which presents 19 successive cases of pneumonia without a death is white dependents "2 to 10 years.")

Population figures are estimated on the basis of allowing 3 dependents to each wage earner. This is considered conservative, as other population estimates have used a reciprocal of from 3.17 to 3.25.

It is interesting to note that while dependents constituted 75 per cent of our population, they gave only 68.1 per cent of pneumonia cases, and though surface employees made up only 17.9 per cent they contributed 21.5 per cent of the total pneumonias; coal miners comprised 4.9 per cent of the population and supplied exactly 4.9 per cent of the pneumonias, while ore miners supplied only 2.2 per cent of the population but 5.5 per cent of the pneumonias (see Chart I).

Expressed in another way, the ore miners gave an annual aver-

CHART III

Occupational Groups  
(Rate in deaths per 100 cases)

age of 11.3 cases of pneumonia per 1,000 ore miners; surface workers 5.6 per year per 1,000; coal miners 4.6 per year per 1,000; coal miners and all dependents a yearly case incidence of 4.3 per 1,000.

It will be observed that the annual case incidence for ore miners is nearly double that for any other group; surface workers come next, and of all wage earners coal miners suffer least.

The story of pneumonia deaths presents an entirely different picture. The fatality rate expressed in deaths per 100 cases was found to be considerably higher for surface workers: 560 cases with 166 deaths, a rate of 29.6; ore miners 143 cases with 33 deaths, rate 23.0; coal miners 127 cases with 29 deaths, rate 22.8; female dependents 994 cases with 180 deaths, rate 18.1; male dependents 779 cases with 102 deaths, rate 13.1 (Chart II).

The frequency with which facts fail to agree with postulates proves the importance of the statistician to industry and the insurance business. Subdividing the groups into white and colored we are struck by another outstanding anomaly (Chart III). In each it will be noticed that the negro has the highest fatality rate with the exception of white surface workers, who have a fatality of 33.5 against 27.8 for colored. Colored ore miners have died at a rate of 26.6 per 100 cases

CHART IV

TENNESSEE COAL, IRON AND RAILROAD COMPANY  
Health Department

Tuberculosis Deaths, by Occupational Groups, 6 Years  
(Rates in annual deaths per 1,000 persons)

while no white ore miner has died. Colored coal miners have died at a rate nearly twice that of the white, 25.0 against 13.0. Among dependents, colored females present a rate of 21.1 against 14.2 for white; colored males 17.5 against 7.2 for white, more than double.

It was not intended to include in this report tuberculosis, but since some facts of interest may be brought out, tuberculosis death rates over the same period and for the identical groups are given (Chart IV).

Although coal miners presented the lowest pneumonia fatality rate of any wage earning group, our experience is that coal miners die from tuberculosis with nearly 3 times the frequency of the average for total population, and have a mortality rate more than  $2\frac{1}{2}$  times that of surface workers. Expressed in deaths per 1,000 persons per year the rates are: coal miners, 1.28, ore miners, 1.14, surface workers, 0.46, total population average, 0.44, dependents, 0.36.

#### CONCLUSIONS

That exposure to sudden and extreme temperature changes is a predisposing factor in the etiology of the pneumonias is, we believe, well established, and is the reason for the unusually high incidence rate of pneumonia among our ore miners—more than twice that of any other group.

In our operations several ore mine openings constitute a single operation. Each operation is provided with a large centrally located bath house at which men do their changing. These houses are constantly at temperatures around 80° F., and many of the miners must walk half a mile or more from mine to bath house. Coming from the mine as they do, in perspiration dampened clothing, they are in certain weather subjected to considerable chilling before reaching a bath house which is kept too hot. Leaving an excessively heated bath house they are subjected to a second chilling on the walk home or car line, which may be a mile distant.

Might not these facts more nearly account for the prevalence of pneumonia among ore miners than any condition under which they work, or the presence of possible pneumoconiosis? The fact that this particular group is more resistant to the destructive processes of pneumonia than are those in whom pneumoconiosis is absent would appear to argue the soundness of such reasoning.

Practically 100 per cent of our coal miners have anthracosis, but their pneumonia incidence rate has been exactly in proportion to their number in the entire population. A rate of 4.6 cases per 1,000, the

lowest of any wage earning group, compares quite favorably with 4.3 cases per 1,000 dependents, which includes all women and children. The fact that coal miners, in our experience, have exhibited the lowest pneumonia fatality of any wage earning group would appear to indicate that anthracosis has had no influence either as a predisposing factor or in contributing to fatality.

That the etiology of tuberculosis is in some way intimately bound up with calcium metabolism appears to be reasonably certain. Calcium metabolism, regardless of diet, is impossible in the absence of sunlight. May it be tentatively suggested that high death rates from tuberculosis among ore and coal miners might more reasonably be attributed to their deprivation of sunshine than to a condition which apparently does not influence other respiratory diseases?

---

## Toxoid Now Supplied

EXPERIENCE having shown that in the immunization of young children toxoid has certain advantages over toxin-antitoxin, the department has for some time been supplying this agent for routine immunizations against diphtheria. By the method of preparation devised in the department's laboratories, the toxoid has a high degree of immunizing power and gives rise in young children to few disturbing reactions. It has, moreover, the additional advantage of containing no serum whatsoever, and cannot, therefore, bring about any sensitization to serum protein.

For the immunization of school children, the department still uses toxin-antitoxin, the mixture consisting of diphtheria toxin and the specific antitoxin derived from goats. The toxin-antitoxin is used there because the first immunizing injection can be made to serve also as a modified Schick test. As about one-half of the school children entering classes are immune, we find we are able by this manner of using toxin-antitoxin to reduce to as much as 50 per cent the children receiving the second and third injections. If we used toxoid we would be compelled first to give the older pupils the Schick test so as to avoid injecting such a large proportion of immune children. Unless otherwise specified, the toxoid will always be supplied. The manner of use of this preparation is the same as that of the toxin-antitoxin formerly used. The dosage is  $\frac{1}{2}$  c.c. if three injections are given and 1 c.c. if only two are given.

Park's studies indicate that with the toxoid now supplied three injections of  $\frac{1}{2}$  c.c. at weekly intervals bring about immunity to diphtheria in over 90 per cent of the cases, a somewhat higher proportion than is ordinarily obtained by the use of toxin-antitoxin. An interval of 2 weeks gives a slightly better result, but the difference is not sufficient to adopt this interval unless it is convenient.—*Weekly Bull., Dept. of Health, New York, 21, 5 (Feb. 6), 1932.*

# Tuberculosis in Young Females\*

W. J. V. DEACON, M. D., F. A. P. H. A.

*Michigan Department of Health, Lansing, Mich.*

IT is an axiom of public health that communicable disease cannot be controlled without knowing when, where, and under what conditions it is occurring. In regard to tuberculosis, as well as other communicable diseases, we know fairly well when and where deaths take place, but we do not know well enough the conditions under which these deaths are occurring.

That the tuberculosis rate has fallen enormously of late years is possibly too well known to need comment. In Michigan the rate of fall has not been so great as in the U. S. Registration Area, possibly because it was much below the registration area at the beginning of the century—195.2 per 100,000 in 1900, and 112.0 in 1920, a decrease of 42.6 per cent.

In Michigan the rate in 1900 was 102.4, or 47 per cent less than for the registration area. By 1920 it had fallen to 85.8, a decrease of 16 per cent, and by 1930 to 60.1, a decrease of 41.3 per cent from the 1900 rate, so that while the fall has not been so rapid, the ultimate rate for 1930 is much below that of the probable rate for the United States. The rate of fall by decades has been as follows: 1900–1910, 4.2 per cent, 1910–1920, 12.5 per cent, and 1920–1930, 30.0 per cent.

That this fall is not accidental is indicated by the rates for the past 10 years:

## MICHIGAN TUBERCULOSIS DEATH RATES PER 100,000

1921 .....	72.3	1926 .....	69.8
1922 .....	68.1	1927 .....	66.0
1923 .....	70.7	1928 .....	67.7
1924 .....	71.5	1929 .....	66.8
1925 .....	66.7	1930 .....	60.1

While there have been fluctuations, the trend has been steadily downward. In spite of this very satisfactory decline, the rate for young females is still much too high. There is, of course, a considerable variation in this factor between communities.

In Michigan the female rate has fallen, but it is still far higher between the ages 15 and 29 than the male rate. It is well recognized that there is a marked difference in the specific death rate for age in

\* Read at a Joint Session of the Vital Statistics and Epidemiology Sections of the American Public Health Association at the Sixtieth Annual Meeting at Montreal, Canada, September 16, 1931.

the two sexes. In the earlier age groups the rates are very similar for both sexes. Beginning, however, with age 10, the rate for females is higher than for males, with a gradually increasing difference until the age group 20 to 24, when it is greatest. From that point it shows some decline for 5 years, and from then on is distinctly lower than the male rate. Between 15 and 29, which is the group that we are attempting to study, the excess of the female over the male rate is very marked. This difference has been recognized and commented upon by many authorities.

From a biological standpoint the higher rate for females at these ages, covering the period of adolescence and early adult life, may be due to the great changes in the organs of the female body which would tend to lower resistance. The important developmental changes, both physical and psychic, that accompany puberty and maturity in females are immensely important factors. The dangers of childbirth must also be considered. The beginning of a disability with fatal termination for those who have an incipient or latent tuberculosis often dates from pregnancy.

This rate phenomenon has been under observation and consideration for some years. All sorts of reasons have been advanced, the most popular theory being that the difference is due to the increased industrialization of women. I believe we must regard most of these theories more as speculations and opinions than logical explanations.

For this reason we have undertaken a study of the occupation of females in this age group who died from tuberculosis, taking the statement on the death certificate in regard to occupation. It is fully realized that this type of study has very decided limitations because tuberculosis is a lingering disease. In many cases the statement "no occupation" conceals the fact that the person may have been gainfully employed up to the time of disability. It is our purpose to present the facts as they appear on the death certificates, supplemented by additional information obtained through a case study made with the assistance of the Michigan Tuberculosis Asso-

ciation. This association assigned one of its staff workers to conduct a field study of the deaths which occurred in 1929, which was comprehensive and gave valuable information.

During the years, 1927, 1928, 1929, and 1930, there were in Michigan 2,630 deaths of females between 15 and 29 due to tuberculosis (all forms). The certificates of 289 contained no statement of occupation, or the statement was too ambiguous to enable us to determine whether the person was gainfully employed. We have, therefore, eliminated these 289 and have considered only the 2,341 in which the statement of occupation was fairly clear. The occupations given were: school, 14.1 per cent, and home, 62.3 per cent—not gainfully employed; industry, 23.6 per cent—gainfully employed.

Of the 2,341 deaths, 1,787, or 76.4 per cent, were indicated as not gainfully employed; 554, or 23.6 per cent, were gainfully employed.

In considering these figures, it must be remembered that this age group of women undoubtedly represents that of greatest gainful employment. While we know of no figures that give the ages of employed women, we do know that among many large groups, such as the employees of the Michigan Bell Telephone Company, the average falls well within this age group. The average age of women employed by this company is 22. It is safe to say that the majority of women who are employed while in this age group are married and are in charge of their own homes by the time that they have passed out of it.

The occupation as given on all death certificates is notoriously inaccurate. Of the 289 certificates discarded, 133 gave "housework"

Fig. 2

### TUBERCULOSIS IN YOUNG WOMEN

The number of Females dying of Tuberculosis, ages 15 to 29, gainfully employed and not employed

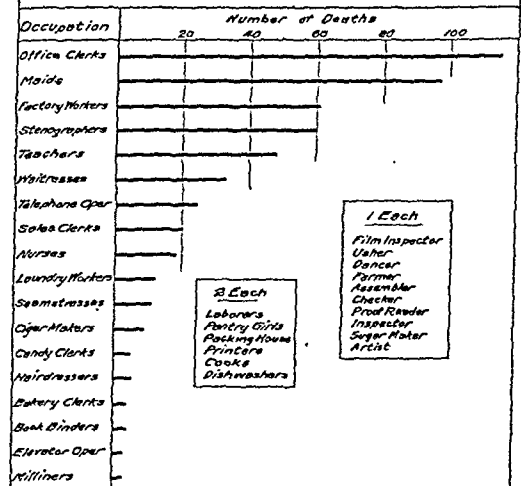

Fig. 3

### TUBERCULOSIS IN YOUNG WOMEN

The number of deaths of young women, gainfully employed, according to stated occupations

or "housekeeper." These terms are of no value because there is no means of knowing whether the persons were employed as housekeepers and doing housework for wages, or were simply housewives working in their own homes. An examination of such of the survey schedules as involved names in this group gave little additional information and failed to change the ratios indicated above.

The 1,787 persons not employed have been divided into 4 groups: no occupation 225, at home 306, students 329, and housewives 927.

The group listed as "no occupation," appear on the death certificates as "none," "unemployed," or "no occupation," but a considerable number of these may have been engaged in some gainful occupation prior to their disability, and in the younger age groups particularly more would have been in school.

The second group, "at home," are just as they appeared on the death certificates. It is probable that the statement in the preceding paragraph would apply equally well here. More than half of the unemployed are listed as housewives, and undoubtedly many in this group were in gainful occupations up to the time of disability or pregnancy.

The listing as "students" is, of course, satisfactory.

The survey schedules were studied for further information and resulted in the change of only 6 statements in this entire group. Where a history of previous gainful employment was brought to light, the case was removed from the unemployed category unless the employment was too remote to have been a possible influence on our findings.

It appears to us that there are two distinct reasons why a knowledge of the employment of women is desirable: (1) to know if the occupation *per se* is an influence on our mortality rates; (2) from an administrative standpoint to know where cases may be found in order that our program for control may be based on a definite foundation.

Of the 554 persons engaged in gainful occupations, there are represented 34 different types of work. Of these, 115, or about 21 per cent, are listed as office clerks. It is probable that more women are employed in this capacity than in any other, but aside from the fact that this is a sedentary occupation, possibly in poorly ventilated offices, we can see no reason for supposing that it would tend to lower resistance to tuberculosis. Occasionally offices are located in factories where there might be contact with fumes and dust, but any influence from these would be remote. The sanitary conditions in offices in which the individual spends about one-third of her time, are as a

whole, probably quite as good as in the average home, in which the other two-thirds are spent.

Next in numerical importance is the number employed as maids. This we regard as the most serious problem in the entire list, not because the occupation would have any deleterious effect on the women so employed, but because of the danger to others. Frequently there are young children in the home and in many cases the contact between the maid and the children is very close, with the constant potential danger to the children. I cannot too seriously urge the consideration of this important factor.

Under the term "factory worker" we have a number of women who are machine operators and do other light mechanical work, occupations which, for women, have grown enormously since the war, but from the large numbers known to be employed, it is probable that the rate is not exorbitant, though the possible harmful effects on women of the deleterious trades such as metal polishing must not be lost to sight.

Stenographers might have been included in the group of office clerks because the type of work is similar, but they are shown separately as that designation appeared on the death certificates. While office clerks, as stated above, may be scattered in small groups through manufacturing establishments, stenographers are usually in general offices where ventilation is liable to be better and working conditions more satisfactory.

Next in numerical importance come teachers. While I think many persons will argue that the possibility of infection from teacher to pupil is somewhat remote, the fact remains that most of us would seriously object to having our children in contact with a teacher who had an active tuberculosis, and most school boards will not employ one so afflicted. The number of deaths in this group is possibly not significant since there were only 48 in 4 years. There are about 30,000 teachers in Michigan in this age group, which would give a specific death rate of about 40 per 100,000, much lower than the rate for the entire group.

Next come waitresses. Here the objection would be based on esthetic grounds rather than on any real danger. There were 33 deaths in 4 years.

Telephone operators and sales clerks occupy the next two places, but it does not seem that the number of deaths is sufficient to represent anything more than an accidental incidence.

The ninth occupation is that of nurse. There were 8 deaths in the 4 years. There are more than 16,000 nurses and trained attend-

ants registered in Michigan, approximately 10,000 on the active list for 1930. It would seem, therefore, that this number hardly represents even a normal expectancy.

Of the other 25 occupations, the numbers vary from 12 to 1. In 10 occupations there were only 1 each and in 6 only 2. Table I gives the details.

TABLE I  
MICHIGAN DEATHS FROM TUBERCULOSIS IN 34 OCCUPATIONS

Book Binders .....	4	Sugar Maker .....	1
Elevator Operators .....	3	Artist .....	1

Of the 2,341 deaths considered, we were able to secure histories from surviving relatives or others in about 400. Some of these were incomplete, or appeared unreliable, and were discarded, but in 340 the schedules were sufficiently complete for our use. These represent a fair sample, being quite evenly divided as to age, geography, and rural or urban.

Of these cases 64 per cent had sanatorium care at some time during their illness, but sanatorium care in itself does not represent much unless the facts as to the stage of the disease at the time they received this care, their length of stay, and subsequent history are considered. These could not be obtained with any degree of accuracy and as a result we must consider this item as one of interest rather than significance. The same applies to the question of medical service. The largest percentage of these cases (29 per cent) had the attendance of a physician for 2 years or more preceding death, while 25 per cent had care for 1 to 2 years; 17 per cent for 6 to 12 months; 23 per cent from 1 to 6 months; 6 per cent for 1 month or less. These figures simply indicate the continuous care immediately preceding death.

In relation to the conjugal state, approximately one-half were single (49 per cent), and the other half married or widowed. About 63 per cent of the married women had given birth to children and thus been exposed to those dangers incident to pregnancy.

A survey in regard to exercise indicated that about one-third took no exercise, the balance some, and in some cases too much.

In 63 per cent of the cases, it was stated that the patient wore warm clothing; in 21 per cent it was thought that the patient did not dress warmly enough, and in 16 per cent it was regarded as doubtful. As the question of sufficiency of clothing is often a matter of opinion, too much reliance should not be placed on these statements.

If we may regard education as a measure of the intelligence of the group, the following figures should be significant: 7.3 per cent had attended college, 34.2 per cent attended high school, and 58.5 per cent had finished or were in the lower grades.

Contacts, as indicated by family tuberculosis history, were definite in 33 per cent of the cases, and in the balance no history of direct family contact was obtained.

A careful study of the previous history of communicable diseases does not reveal anything of significance in the absence of a control group. For instance, 63.7 per cent of the cases gave a history of measles but we have no means of knowing that any other group which did not die of tuberculosis would not show as great or a greater percentage.

It is interesting to note remarks on many of the survey schedules in regard to pregnancy and influenza. There were many notations to the effect "poor health since influenza (1 year)"; "well until pregnancy (1½ years)"; "miscarriage, never well after"; "following influenza and pneumonia."

Just what effect influenza may have in the lighting up of old tuberculous lesions is an interesting question, but a study of these cases without a control group would be of doubtful value. There seems to be no doubt, however, that the strain of childbirth does lower resistance and the persistence of even slight illness following pregnancy should suggest very careful diagnosis and watchful care.

From this showing it must be very evident that industrialization is not an important factor in the mortality from tuberculosis among young women. Personally I can see no reason to believe that there is any more hazard involved when a young woman leaves her home, whether she goes to school or into an office, in most cases working not to exceed 8 hours under favorable sanitary environment. Whether we consider housewives, employed persons, or students, the problem is in the home and everyone who has experience in public health work realizes that this is the most difficult group to reach.

It is probable that more intensive work in the schools in the higher grades would be of value. Most efficient work is being done in the

lower grades for the control of all types of communicable diseases but there is a decided tendency to neglect the junior high school, the high school and the collegiate groups, and these are the groups that passing out of the schools go into the home and from which the excess mortality of the next few years is recruited. It is, of course, much easier to reach the group collectively in our educational institutions than in the home.

I referred to the developmental changes related to puberty and maturity as both physical and psychic. The physical changes while great, should be regarded as physiological and not pathological, but it is the psychic condition that accounts for such foolish fads as dieting, insufficient clothing, late hours, tobacco and alcohol, all or any of which may be factors in lowering resistance to disease. These habits can be improved only by education, and if our message can be carried into the higher grades while the mind of the student is still plastic we may reach the home of tomorrow, reap the harvest of saved lives, and the goal of lower death rates for which we are all striving.

We have tried to show that the problem is in the home. We have not offered a plan for reaching the home except the suggestion that work in higher grades of school be emphasized.

We are satisfied that gainful occupation *per se* is not a factor in the high rates for tuberculosis among young women, but we must consider the influence of certain diseases and of pregnancy in relation to these rates and this problem offers an inviting opportunity for research.

---

## Germany: Prussia—Family Income and Infant Mortality

FOR the purpose of ascertaining the relation between family income and infant mortality a study was made in Prussia of 297,000 deaths in the 1st year of life which took place in 1913 and 1925–1929, inclusive. The deaths were divided into four groups according to the family income. Although the generally prevailing downward trend of infant mortality was observed in all four groups, there was a considerable difference every year in the four income groups. The infant mortality rate increased steadily for each group with the decrease in income; for instance, in 1913 from 66 per 1,000 live births in the highest income group to 214 in the lowest; in 1927 the figures were 36 and 142, respectively, and in 1929, 34 and 135, respectively.—*Arch. f. sociale Hygiene und Demographie*, Berlin, 6, 2: 89, 1931.

of each type per man per day in the individual prisons was calculated for each month and for the year, then the per man per day consumption for the 5 prisons for each month and for the year was calculated. Using these averages, adjustments were made, in consultation with Dr. Hazel K. Stiebeling of the Bureau of Home Economics, to furnish what may be considered a satisfactory diet not only from the point of view of nutrition but also of prison conditions. A schedule of food groups, type foods, and the amount of each type (Table I) was prepared for estimating the money value of food for federal prisons.

TABLE I

A BASIS FOR ESTIMATING THE MONEY ALLOWANCE FOR FOOD FOR FEDERAL PRISONS PER MAN PER DAY \*

Food Groups	Food Type for Price Basis	Amount lb.
Meats and fish.....	Beef	0.75
Fats.....	Oleo	0.15
Flours, starches, cereals.....	Flour, white	0.80
Dairy products.....	Milk	1.00
Eggs.....	Eggs (at 1 1/2 lb. per doz.)	0.03
Sugars and syrups.....	Sugar, granulated	0.25
Beverages.....	Coffee	0.10
Leafy, green and yellow vegetables and tomatoes.....	Cabbage	0.60
Roots and tubers.....	Potatoes	1.00
Beans and peas, dried.....	Beans, navy	0.10
Fruits, fresh or canned.....	Apples	0.15
Fruits, dried.....	Prunes	0.08
Spices.....	Salt	0.10
Miscellaneous food adjuncts.....	Yeast	0.015

\* These quantities of food could well be approximated on the average during a month. It is not expected that they will be met in detail each day.

These values were suggested after considering, as indicated above, the kinds and amounts of food eaten in federal prisons for over a year, the kinds and amounts that should occur in economical diets, and the kinds needed to lend palatability to an economical diet.

The contract prices of the various type foods have been applied to the actual quantities of various food groups eaten by prisoners and

\* Without a 5-10% increase  
† Correction of amount spent to correspond to 0.75 lb. of meat

to the amounts of foods indicated in the schedule, and comparisons made between the two sets of data and the actual amount of money spent for food for 2 major prisons at monthly intervals throughout the year. The results for these prisons are contained in Table II.

The results agree roughly within 90 to 95 per cent of the actual money spent for foods. The greatest errors appear when there are variations in consumption of the leafy, green and yellow vegetables and the fruits. It is believed that the estimated cost of this schedule of foods plus a probable maximum of 10 per cent will amply cover the cost of food per man per day.\*

The value of this ration as indicated is:

Energy value, 3,955 calories

Weights of food constituents as grams per man per day

Proteins .....	140
Fat .....	116
Carbohydrates .....	545
Calcium .....	0.93
Phosphorus .....	1.62
Iron .....	0.028

With regard to the food types used for the calculation of prices, the foods selected are those that have occurred in prison diets most of the year and are used in relatively large amounts. There are two places where it may in the future be advisable to select a type of food for each quarter or half of the year rather than one type for the whole year in order to obtain a better evaluation of the cost of the rations—the leafy green and yellow vegetables, and fresh fruits. Seasonal variations in cost and consumption of the type food are particularly noticeable in these groups.

From our studies of prison dietaries and their composition,<sup>1</sup> we find three points that need especial attention: (1) palatability, (2) the uses of vegetables, and (3) the high phosphorus consumption.

Palatability plays an important rôle in any diet. In mass feeding where there is little individual choice of foods palatability becomes one of the prime factors in contentment. Palatability and attractiveness are attained through the use of the natural flavors of food, mode of preparation, or method of service. Meat has an appeal to most appetites and adds flavor to many bland dishes. It also represents a considerable proportion of the cost of any diet. The quantity of meat chosen for the ration,† 0.75 lb. per man per day, is somewhat

\* The calculation of the cost of the ration by the Bureau of Home Economics, U. S. D. A., at current lowest retail prices in 12 cities in the United States for March, 1931, showed a variation in cost of from \$0.462 in Detroit to \$0.320 in Kansas City (with a mode of \$0.36 to \$0.37). It represents therefore a moderately priced diet adequate in composition.

† The amount given represents all types of meat purchased, but particularly carcass meat.

less than appears to be agreeable to the average prison inmate. The quantity has been reduced only because the cost of a larger amount is not justified, especially with the increase in fruits and vegetables.

There is a need for greater use of vegetables in prison dietaries as carriers of salts and vitamins and also to introduce variety into the meal. The successful increase in the use of vegetables depends upon skill in their preparation or their combination with other foods. The errors of preparation are often those of overcooking or failure to reduce the vegetables to fragments that are appetizing. Adequate facilities for preparation and cooking are essential.\*

An economical diet containing considerable amounts of grains and meat is likely to contain a disproportion of calcium to phosphorus. The proposed inclusion of 1 pound of milk or milk products and the green vegetables has brought the ratio of calcium to phosphorus to approximately 1 to 2.† While we do not know the best ratio with any surety, it is probable that a wider ratio is not desirable. Milk is not especially effective in correcting the deficiency since its ratio is roughly 1:1. From certain aspects it appears desirable to add calcium carbonate or lactate under conditions where its presence will not be particularly evident, such as in bread, salt, or stews.‡

The classification of foods into groups has another use—as the basis for evaluating the character of the diet of prisoners. This general grouping of foods, with certain modifications, has been applied to the cost accounting system of the federal prisons so that each month's report contains in addition to the cost of food consumed the average weight per man per day of the various items, based upon the number of inmates assigned to the mess. For this purpose the groups were in some cases subdivided. Table III gives the grouping and code number for each of the groups. With the information obtained it will be possible to evaluate roughly the adequacy or inadequacy of the prison ration and to recommend modifications from month to month. An approximation of the chemical composition and vitamin content of the diet may be readily obtained. While carrots might properly be classified under the yellow vegetables it seems more logical to put them under the roots and tubers.

The evaluation of a diet on the basis of weights of food groups is subject to misinterpretation with regard to the variety of food offered

\* In the new federal institutions now under construction or projected the facilities provide adequately for diversified preparation and cooking.

† It is interesting to note that in the R. O. T. C. mess, included in Table IV, the ratio of calcium to phosphorus was approximately 1 to 2 in spite of the milk and vegetables used.

‡ We have found in connection with the Bureau of Home Economics, U. S. Department of Agriculture, that a palatable bread can be made with calcium carbonate in a potato flour prepared by the spray process.

TABLE III

CLASSIFICATION OF FOODS

.01 Meats and fish, canned Canned corned beef, canned salmon, canned sardines, etc..	.12 Potatoes and sweet potatoes
.02 Meats and fish, cured Bologna, corned beef, dried beef, frank- furters, ham, bacon, etc.	.13 Roots Beets, carrots, onions, parsnips, ruta- bagas, turnips
.03 Meats and fish, fresh Beef and veal, fish, mutton and lamb, pork, poultry and fowl, boned meats, etc.	.14 Leafy, green, or yellow vegetables Asparagus, beans (string), cabbage, cauliflower, celery, collards, corn (fresh and canned), cucumbers, eggplant, greens (mustard, rape, spinach, turnip), lettuce, peas (green and canned), pep- pers (green), pumpkin, radishes, rh- barb, sauerkraut, and squash
.04 Lard and cooking oil Lard, pure and substitute, and cooking oils, etc.	.15 Tomatoes and catsup
.05 Butter and margarines	.16 Dried beans, dried peas, and nuts
.06 Flours, starches, and cereals Barley, bran, bread, crackers, cream of wheat, corn flakes, corn meal, flours, grape-nuts, hominy and hominy grits, oat meal, puffed wheat and other wheat cereals, rice cereals and cornstarch, etc.	.17 Fresh fruits and berries
.07 Spaghetti, noodles, macaroni, rice as such, and vermicelli	.18 Canned fruits and berries
.08 Dairy products Fresh, canned and powdered milk, cheese, and ice cream, etc.	.19 Dried fruits
.09 Eggs Eggs, fresh and preserved	.20 Miscellaneous food adjuncts Ammonium carbonate, baking powder, coloring, cream of tartar, extracts, gelatin, baking soda, tiptopping, and yeast
.10 Sugar and syrup Sugar, syrup, jelly and similar foods	.21 Spices, relishes, and sauces Allspice, bay leaves, caraway seed, celery salt and seed, chilli pods, powder and sauce, chop suey sauce, cinnamon, cloves, cummin seed, curry powder, garlic, ginger, horse radish, mace, mustard, nutmeg, paprika, pepper, sage, salt, table sauce, thyme, vinegar, Wor- chester sauce, and pickles
.11 Beverages Coffee, tea, and cocoa	

unless some knowledge is had of the distribution of food substances within a group. Some idea of variety may be obtained from the menus. If those used do not prove satisfactory—and it is possible that a menu may be entirely misleading—then it may be necessary to resort to a special report on the variety of foods furnished under one or more of the various food groups. On the other hand, with a knowledge of the activities of a particular steward or cook it will seldom be necessary for special consideration.

Recently one of us has had the opportunity of examining the food consumption of a R. O. T. C. mess at the Field Medical Service School, Carlisle, Pa., under the supervision of Major Charles T. Spruit, M. C. The type of mess was such that there was probably more than the average consumption of vegetables and fruits. The data obtained for 2 weeks and also the Garrison Ration of the Army, are added, with the permission of the Surgeon General of the Army, in Table IV for the purposes of comparison with the proposed prison ration. With regard to the Garrison Ration it is recognized in the army that it

TABLE IV

WEIGHT OF TYPES OF FOOD CONSUMED BY THE R. O. T. C. MESS, CARLISLE BARRACKS, PA., JUNE 14-21 AND JULY 7-13, TOGETHER WITH SIMILAR DATA PREPARED AS A BASIS FOR RATIONING FEDERAL PRISONERS AND THE PRESENT GARRISON RATION

	R. O. T. C. June 14-21	R. O. T. C. July 7-13	Garrison ration U. S. Army	Proposed Prison
	lb.	lb.	lb.	lb.

is not intended to represent the actual food consumption of a soldier but is a basis of determining an allowance of money with which food may be purchased for the mess. The value of certain items was increased beyond what the average man is likely to eat in order to supply additional money for the purchase of green vegetables and a variety of meats and other food. The Garrison Ration does not necessarily represent the most desirable distribution of quantities of food. The basis of estimating the cost of the army ration and the proposed prison basis of estimating cost differ in that the prison basis is intended to cover the actual cost of a diet that is adequate and permits a reasonable variety of food through varied methods of preparation rather than through a variation of kinds of food.

# Experimental Poliomyelitis

## Its Contribution to Our Knowledge of the Human Disease\*

S. D. KRAMER, PH. D., M. D.

*Department of Preventive Medicine and Hygiene, Harvard Medical School,  
Boston, Mass.*

THE development of our knowledge of poliomyelitis begins with the separation of the clinical syndrome from unrelated but more or less crippling diseases. Heine, in 1840, and Medin, in 1890, gave us the first clear clinical pictures and, to a lesser extent, the pathology. Caverly's report of the outbreak in Vermont in 1894 and Wickmann's report of the Swedish outbreak in 1905 extended the earlier clinical and pathological observations and showed clearly that paralysis was preceded by a febrile stage. These authors pointed out that many cases did not result in paralysis and suggested the mode of spread of the virus. They were the first to indicate clearly that in many instances contact can be proved, thus giving us the beginning of our present concept of the epidemiology of the disease.

In 1909 Landsteiner and Popper succeeded in transmitting the disease to the monkey. This marked the beginning of progress in the experimental study. Landsteiner and Popper's work was quickly verified and extended by Flexner and Lewis, and Strauss and Huntoon. Infection in the monkey was first accomplished by intraperitoneal inoculation with a suspension of spinal cord from a human source, but it was soon found that this could be done in a variety of ways—intramuscularly, subcutaneously, intranasally, intrathecally, directly into the nerve sheath, and intracerebrally. This last remains the method of choice when positive infection is desired. The animals so inoculated develop a more severe form of the disease with almost 100 per cent fatal outcome, whereas those infected intranasally tend to a higher rate of recovery. Innumerable passages of the original human strains have now been carried over from monkey to monkey and the strains now employed in most laboratories are in large part passage from the

---

human material of a decade or more ago, although many new ones have been added.

That the infective agent of poliomyelitis belongs to the group of so-called filterable viruses is now almost universally accepted. The unseen agent not only passes readily through filters, but fulfils the more characteristic property of filterable viruses—their inability to multiply away from living tissue. Diligent search for organisms by many workers has failed to verify Rosenow's and Nuzum's findings. Except for the suggestive work of Flexner, Noguchi and Amoss and more recently of Long, Olitsky and Rhoads with the globoid bodies, all attempts to grow the virus outside of the living body have failed. In laboratory work, the virus is obtained by grinding a piece of the glycerolated cord, or of cord of a freshly killed animal, with fine sterile sand to which normal saline in the ratio of 1 gm. cord to 20 c.c. saline has been added. The suspension is then either centrifuged and the supernatant fluid used, or filtered through a Berkfeld candle.

The virus withstands glycerolation for years. Desiccation over KOH for weeks fails to alter the virulence appreciably. It is resistant to phenol in 0.5 per cent strength, but  $H_2O_2$  and  $HgCl_2$  have a destructive action, and heating at  $65^\circ$  for half an hour destroys it. Freezing temperatures as low as  $-2^\circ$  to  $-4^\circ$  C. for weeks do not affect it, and at  $4-5^\circ$  C. it can be kept almost indefinitely. Clark, Schindler and Roberts have recently found the virus to survive saturated NaCl solutions ordinarily destructive to living cells.

The virus is readily rendered non-infective by immune serum. The action of the immune substance does not seem to be of a virucidal nature, however, but simulates the toxin-antitoxin phenomenon of diphtheria. By means of cataphoresis the non-infective mixture of virus-immune serum can be dissociated, the virus migrating and concentrating at the anode, indicating an electronegative charge. That the neutralizing mechanism obtains for a short time at least in the animal body was shown by Olitsky, Rhoads and Long, who were able, by this method, to separate the virus from the cord of a recovered animal 23 days after infection, although the cord suspension before cataphoresis proved innocuous by intracerebral inoculation into normal monkeys. Burnet and Macnamara have recently suggested the existence of immunologically distinct strains of the poliomyelitis virus. They believe their Australian strain differs immunologically from the Flexner and Aycock strains. The paucity of data and the obvious differences in the virulence of the strains compared leave considerable doubt of the existence of any fundamental immunological differences in those studied.

The experimental disease in the monkey (*Macacus rhesus*) is a faithful clinical and pathological reproduction of the human disease. The monkey remains the one animal in which the human disease can be reproduced. Immediately following inoculation, the animal appears well and continues to act normally for several days. The first indication of infection is an elevation of the temperature of from  $1^{\circ}$  to  $3^{\circ}$  above the normal range of the animal, which varies between  $100^{\circ}$  and  $103^{\circ}$  F. The rise is constantly found and precedes the appearance of paralysis 1 to 3 days. Shortly after the rise of temperature the animal begins to refuse food and shows a disinclination to climb about the cage. About the same time, the fur becomes ruffled and frequently a tremor develops. After 24 to 72 hours the temperature reaches a maximum and then drops sharply. As the maximum is approached and reached, the animal shows obvious signs of illness, remaining hunched in a corner, the fur ruffled, tremor present, and food being generally refused.

Paralysis is usually first noted with the beginning of the drop in temperature. As in the human disease, the involvement of parts follows no rule and is characteristically haphazard. Paralysis may begin in either upper extremity and extend to all, or in one or both legs and extend upward, till the animal is completely paralyzed. With the appearance of the paralysis the animal becomes prostrated and the temperature becomes subnormal. At times a drop of  $6^{\circ}$  to  $10^{\circ}$  within 24 hours is observed. This severe involvement and collapse is noted in well over 90 per cent of animals infected by the intracerebral route and death follows in a few days.

Although with careful nursing life can be maintained for several days or weeks, death eventually occurs from asthenia or involvement of the entire breathing apparatus (intercostal muscles and diaphragm). Deaths due to cerebral and bulbar involvements have been described, but I have failed to observe such types in the past 5 years. Between 5 and 10 per cent of animals so infected recover with varying amounts of paralysis. Upon recovery they return to normal activity in a few days to a week or two, hampered only by a residual paralysis. The intranasal and other routes of infection yield a somewhat higher number of recoveries. As in the human disease, paralysis is frequently followed by deforming contractures.

The pathologic lesions found at autopsy are entirely analogous to those in the human form. Irrespective of any difference in the mode of infection in man, and the route of inoculation employed in monkeys, the lesions are characteristic and analogous. The outstanding characteristic lesions are found in the central nervous system. On

first view, the macroscopic changes are not particularly striking. The cord and brain show edema and congestion of the meninges. The edema of the cord may at times be somewhat more marked in some areas and appear patchy. On sectioning the evidences of edema are more pronounced—the substance pouts above the edges, has a darker gray-pinkish appearance and not infrequently minute hemorrhages are seen. The brain and pons show less involvement except for meningitis at the site of inoculation.

Changes in other parts of the body are not characteristic. Some cloudy swellings of the large parenchymatous organs are frequently seen and these changes also are observed on histological examination. The greatest changes outside the central nervous system are found in the lymphatic structures throughout the body. These are more readily noticed in the mesenteric lymph nodes, which are somewhat enlarged, and on section show necrotic areas and considerable edema and infiltration. This swelling often extends to Peyer's patches, and has given some ground to the notion of an intestinal route of infection.

The characteristic changes, however, are found on histologic examination of the cord and, to a lesser extent, parts of the brain. The lumbar and cervical segments usually present the greatest changes. In the early stages of paralysis a diffuse infiltration is seen involving both posterior and anterior parts of the gray matter of the cord. The type of cells varies with the stage of the disease, being in large part polymorphonuclear leukocytes in the earlier stages, soon replaced by cells of the lymphocytic series and microglial cells.

It is peculiar and striking that whereas the infiltration of phagocytic cells seems general, involving both the anterior and posterior parts of the cord, it is the anterior horn cells almost exclusively that undergo degenerative changes. The first change noted in the neurons is central chromatolysis, followed by complete solution of the Nissl substance. The nuclei and cytoplasm then swell and become very pale, and the nuclei disappear. At times the nuclei shrink, stain more darkly and assume an eccentric position in the cells. The cytoplasm then begins to stain irregularly, becomes reticulated and vacuolated and often contains several polymorphonuclear leukocytes. Granular degeneration follows, and all internal neuro-fibrillar structure is lost. With the onset of degeneration, neuronophagia proceeds. The site of the former neuron is soon filled by polymorphs, lymphocytes and glia cells. Very rapidly the polymorphonuclear leukocytes disappear and the microglia undergo enormous proliferation, these cells soon forming the bulk of the exudate in the gray matter, and are found clustered about the anterior horns indicating the former site of the neuron.

It has been suggested recently that our concept of the manner of attack of the virus on the anterior horn cells may be erroneous. Our belief, largely based on the work of Flexner and his coworkers, has been that the virus reaches the cord first through passage or propagation along the lymphatics and vascular system, thus reaching the nerve elements, and because of the resultant perivascular reaction the anterior horn cells suffer from ischemia and die.

In several recent publications, Fairbrother and Hurst renew the concept first promulgated by Leiner and v. Wiesner and present data based on histologic studies of the experimental disease to indicate that the action of the virus may be directly on the cells, and that this toxic action antedates the generalized infiltration and perivascular cuffing found at autopsy in human cases. The work of these authors, although carefully carried out, is yet to be confirmed. The researches of the earlier workers of the inter-passage of both virus and immune substances from blood stream to spinal fluid and in the reverse direction under specified conditions remain, however, convincing evidence of the importance of these fluids in transporting the virus from the portal of entry to the central nervous system.

Sufficient experimental evidence has been accumulated to indicate that the virus may readily enter the body through the nasal mucous membrane. The significance of these findings in the spread of the disease is obvious. In addition, epidemiological and immunological studies have consistently indicated contact and carrier factors in the spread of the virus.

It was found early that animals that had recovered from an attack resisted reinfection by any route. The time of the development of this protection varies. Although it has been observed in the acute stage of the disease it usually does not appear until a few weeks have elapsed.

The nature of this resistance was first shown by Landsteiner and Levaditi, who mixed the serum from a recovered monkey with the virus. They found that upon injecting a portion of this mixture containing an infecting dose of the virus intracerebrally into a normal monkey, the animal failed to succumb. Similar experiences were encountered when the serums of recovered patients were used in place of convalescent monkey serum. These findings have been confirmed many times and give us, within certain limits and when adequately controlled, an experimental test for immunity to the disease. By means of this test, it has been possible to carry on epidemiologic investigations comparable to studies in diphtheria by the Schick test. It has been possible, for example, to establish the incidence of im-

munity in the general population, urban and rural, in the south and north. It has also been possible to show a close correspondence between the epidemiology of poliomyelitis and other contact diseases, particularly with diphtheria the epidemiology of which is well established. By this test we have recently established the mechanism through which this extensive immunization of the population may be accomplished; namely, as in diphtheria, through a subclinical route. We have shown that the immune substance is passively transmitted from mother to new-born precisely as in diphtheria and measles. The neutralization test has been of inestimable value in establishing the epidemiology of poliomyelitis on a sound footing and has helped to clear up many of its mysterious aspects.

From the first observation that the serum of recovered animals and patients had an inhibiting action on the virus, efforts have been made to establish the therapeutic value of convalescent serum. Although the literature is replete with favorable reports, and we in Massachusetts have used it for the past 5 years with apparently favorable results, its value is not yet established. Nowhere in the literature is there evidence that the serum was employed in a critically controlled experiment, i.e., the treatment of alternate cases diagnosed in the pre-paralytic stage. In a disease such as poliomyelitis where the outcome varies within such wide limits, and the incidence and extent of paralysis is unpredictable, nothing short of an alternate case experiment on an adequate series can be used as conclusive evidence of the value of any therapeutic agent. We have ample evidence that the serum is not of absolute value even when administered in large quantities in the earliest pre-paralytic stages. Whether or not it is of *any* benefit in treatment of the disease is as yet in doubt.

In spite of doubt concerning its value, efforts to obtain an adequate supply and diligent search for an animal source of a hyper-immune serum have continued. Our findings of a high rate of immunity in normal urban adults, whose serum, so far as is known, is equal in potency to convalescent serum, might vastly facilitate the matter of supply.

Recently Pettit's immune horse serum experiment has been revived by Fairbrother, and Fairbrother and Morgan abroad, and by Weyer, Park and Banzhaf in this country, and in the goat serum of Howitt another source of immune serum may be made available. Efforts have been made to test the relative potency of these serums. The effort to obtain a large supply of immune serum is perhaps premature when it is borne in mind that the fundamental question of whether or not immune serum works at all has not been settled.

Convalescent serum therapy, however, needs no apology. The serum has a definite inhibiting effect on the virus and from this experimental evidence alone it represents the most logical form of treatment. The results of the therapeutic use of immune serum in the monkey have not been encouraging. We have shown that the animal goes through a stage quite analogous to the pre-paralytic stage of the human disease, and if the serum is administered in large doses during what seems to correspond to this, there is no apparent interruption in the course of the disease. The animal goes on to paralysis and death as do the controls. Furthermore, when the cords of the animals are tested, they still contain active virus. It might appear from such experiments that convalescent serum would have no effect on the human disease; but such a conclusion does not necessarily follow, for the reason that the experimental disease in the monkey is a far more severe infection than that seen in man.

More hopeful results are obtained in protection experiments. Flexner and his coworkers, in 1910, were able to protect animals for 24 to 48 hours by the intraspinal administration of human convalescent serum. Rhoads has recently obtained protection from infecting doses for as long as 6 days by a similar procedure. Weyer, Park and Banzhaf report successful protection by intramuscular administration of immune horse serum, but since they used the somewhat uncertain nasal route of infection and no detailed protocols are given, it is difficult to determine if all the experiments were conducted in a parallel manner. Since intranasal instillation of virus does not uniformly result in disease, in any experiment employing this route of infection parallel and adequate numbers of control animals are essential. In our own experience with intranasal infection over a period of years, we have come to realize the uncertainties of this method. Although nearly all animals can ultimately be so infected it cannot always be accomplished by 1, 2 or 3 instillations; at times many may be needed before a "take" is effected. Whether this variation is entirely due to potency of virus or whether individual differences in susceptibility are factors is not known.

A number of attempts have been made to determine the relative strength of the serums available—human convalescent, adult human, and immune horse and goat. Here again one is treading on uncertain ground. The technic of the test as first employed by Flexner and Lewis is, with slight variations, that employed by most workers. This consists of mixing a varying amount of 5 per cent centrifuged suspension or filtered material with varying amounts of the serum to be tested. They are well mixed, incubated at 37° C. for 2 hours, and

kept overnight in the ice chest. An amount of the mixture sufficient to contain the usual infecting dose of virus is inoculated intracerebrally.

A number of factors have militated against refinements in the original technic. One of the chief difficulties is in establishing and working with a minimal infecting dose of virus. An average monkey cord weighing 7 or 8 gm. is soon used up so that it is not possible to carry on a long continued series of experiments with a single specimen of virus. The virulence may vary with individual cords, which necessitates often repeated expensive titration of individual cords.

While the results of a titration of an unknown serum may be comparable and valid for any single experiment, they may not be at all comparable with those of a similar experiment in which another specimen of virus or serum is employed. That such errors may and actually do arise is seen in the independent attempts at titration carried out by Shaughnessy, Harmon and Gordon in Chicago, and Weyer and Park in New York on human convalescent and human normal serums. The former authors found what they thought was a significantly higher titer of immune substance in the normal human serum over the convalescent, whereas Park and Weyer maintain that normal serum has only one-half the neutralizing power. The protocols of both groups seem fairly clear-cut and may be valid for the conditions and reagents used, but it is obvious that their results were not comparable, and therefore could not be used for purposes of generalization.

We have attempted to carry out such titrations from time to time in the past 6 years and as the number of tests grew it was realized that both the technic and reagents were much too uncertain and variable to permit of generalizations. Unfortunately neither the technic nor the reagents have reached the refinement which would allow such precision of titration as is possible, for example, in diphtheria toxin and anti-toxin.

Successful experimental protection naturally raises the question of such protection in man. So far, the only convincing evidence of protection is observed when the serum is administered intraspinally (Flexner *et al.*; Rhoads). Whether intramuscular injections of immune serum give a passive immunity has not been proved.

Many attempts have been made actively to immunize the experimental animal. Because of the close analogies between the virus of poliomyelitis and that of rabies, attenuation of the poliomyelitis virus by drying was attempted a number of times. Landsteiner and Levaditi believed that they could immunize animals by the Pasteur technic, but others, notably Aycock and Kagan, found this method uncertain, a number of their animals coming down with the disease.

Other efforts have been made to attenuate the virus, some by heating for short periods of time (Abramson, Leiner and v. Wiesner, Landsteiner and Levaditi), or by exposure to the action of weak solutions of phenol. The results of these methods have been uncertain and hazardous—some animals were protected against subsequent infection, some failed to develop any protection, and others came down with the disease in the course of immunization. Aycock and Kagan found the safest and most constant results to be the multiple intracutaneous method, using an active virus. We have repeated these experiments many times, and recently Rhoads has successfully immunized animals by this route at a single sitting, injecting large amounts of virus over a large skin area.

Recent work with viruses indicates that they are not destroyed by the specific antiserum, but such serum acts as a neutralizer or inactivator, the phenomenon being similar to the neutralizing action of antitoxin on the toxin of diphtheria. It was found that this union could be severed by such simple procedures as dilution or filtration. For poliomyelitis virus the similar nature of the antiserum-virus combination was shown by Olitsky, Rhoads and Long, who were able to recover the virus in a potent form by cataphoresis from a neutralized mixture. The use of neutralized mixtures for the production of active immunity was first suggested by von Behring. Andrews, by employing neutralizing doses of virus and immune serum mixtures, was successful in producing immunity to vaccinia in rabbits; and Rhoads, by administering large doses of neutralizing mixtures of virus and immune serum intradermally, successfully vaccinated a certain number of monkeys against poliomyelitis (none of the animals, successfully vaccinated or not, showing any evidence of illness during the process). We have repeated these experiments, confirmed the results, and have developed a sufficiently high state of immunity to resist intracerebral inoculation of a large dose of a potent virus. Brodie and Goldbloom have reported successful immunization by a similar method.

Rhoads, utilizing the adsorption and inactivating properties of aluminium hydroxide, successfully immunized a series of animals by subcutaneous inoculations of the inactivated mixture. None of the animals showed any sign of illness throughout the vaccination. It appears, therefore, that we have available a safe, sure technic for the artificial production of immunity in experimental animals which may in time be developed into a suitable means for immunizing human beings. The advisability of such a procedure for universal immunization, in view of the low incidence of the disease, is problematical. Since the incidence of the disease, even in the worst outbreak, is seldom

over 1 or 2 per 1,000 population, any attempt to immunize against it would mean treating large numbers who would escape, in order to protect the few who would succumb. There is increasing evidence that physiologic differences in the host may be a large, or even a determining, factor in the outcome of an initial exposure to the infective agent. Too little is known concerning such physiologic alterations, and until more concrete data are obtained on this fundamental factor, it may be desirable to follow the orthodox procedure of active immunization if such a method can be safely applied. Although such a procedure might not be of general application during inter-epidemic years, it might be a useful weapon at the time of a severe outbreak.

# Basic Records for Use in a County Health Department<sup>\*</sup>

JOHN COLLINSON, M. D., DR. P. H., F. A. P. H. A.

*Chief, Bureau of Vital Statistics, State Department of Health, Baltimore, Md.*

CERTAIN basic information is needed by a county health officer in order that he may organize his work intelligently and constructively, may handle emergencies as they arise, and evaluate results.

Suggested forms on which the necessary data may be recorded and summarized were submitted with the paper presented by the writer in Montreal. For convenience of arrangement the forms were grouped under the following headings:

- A. Communicable Diseases and Communicable Disease Control
- B. Prenatal and Maternal Care, Care of the Infant, the Preschool and the School Child
- C. Births, Deaths and Causes of Death

It is necessary that the health officer use the United States Bureau of the Census populations of his state and county, by age, sex, color or race, for the background of record keeping. Summarized records of reported notifiable diseases, of births, deaths and causes of death for the state and each county should be supplied him monthly by the state bureau of vital statistics to check the correctness of his records and for comparison.

A description of the forms submitted follows:

## *A. Communicable Diseases and Communicable Disease Control:*

1. Individual case card for the use of physicians. To be supplied in quantity to all physicians in general practice in the county, in order that they may report promptly to the health officer each case, or suspected case, of a notifiable disease attended, or brought to their attention.

2. Epidemiological record forms. Examples of forms for use in the investigation of diseases according to mode of transmission:

### *a. Naso-pharyngeal discharges*

Example—Diphtheria—Card includes a clinical history of the case, a census of

<sup>\*</sup> Abstract of paper read before the Vital Statistics Section of the American Public Health Association at the Sixtieth Annual Meeting at Montreal, Canada, September 14, 1931.

the household, extra-household associations, suspected or positive cases of diphtheria in associates, prophylaxis and general environment.

*b. Excreta-borne*

Example—Typhoid fever—Card includes a clinical history of the case, a census of the household, general environment, details of patient's exposure to possible sources of infection, sources of food and water supply.

*c. Diseases of animals transmitted to man*

Example—Undulant fever—Card includes a clinical history of the case, census of household, general environment, places and kind of work and dairy products used.

*d. Insect-borne*

Example—Typhus—Spotted fever—Card includes a clinical history and examination of the patient, exposure to rodents and insects, census of household, home and occupational environment.

3. Tuberculosis

*a.* Examination and clinic report—Card includes the family history, previous history, present illness, and physical examination.

*b.* Individual case record—Card includes information on contacts and notes of visits by public health nurse.

4. Notifiable diseases, cases and deaths by month of occurrence. Tabular record form.

5. Reports of individual physicians, by months and years. Tabular record form.

6. Spot map for indicating location of cases of notifiable diseases.

7. Immunization record forms for protection against diphtheria, scarlet fever, and typhoid fever. Card includes record of authorization.

*B. Prenatal and Maternal Care, Health of the Infant, Preschool and School Child:*

1. Maternal History—Card includes history of previous pregnancies, prenatal and obstetrical care, postnatal visits and condition on discharge.

2. Infant Record—Card includes history of living conditions, kinds of food taken, illnesses and records of examinations, corrections and immunizations.

3. Preschool and School Record

*a.* Individual record—Card includes past history, findings on examinations, corrections and immunizations.

*b.* Summary of defects found and corrections made in each school. Tabular record form.

*C. Births, Deaths and Causes of Death:*

1. Forms on which to make exact copies of original certificates of births and deaths. These should be filed in the office of the health officer.

2. Cross index cards for births. These are useful in large counties.

3. Tabular record of live births; by attendant, color and month; with totals for current and previous year.

4. Monthly tabular record of deaths from certain causes and classes of causes; by color and age groups.

5. Monthly tabular record of infant deaths under 1 year (exclusive of still-

births) from leading causes and classes of causes; by color, sex and age periods.

6. Monthly summary of maternal mortality; by causes, by color and month, with totals for current and previous year.

7. Departmental record of individual physicians and midwives; giving the number of births reported by years and months.

NOTE: Because of the cost of printing, reproductions of the forms are omitted from this article. Copies can be obtained from the author upon request.

## Mental Hygiene and the Depression

WHAT is the depression doing to the nation's mental health? Has there been an increase in mental diseases that can be ascribed, directly or indirectly, to prevailing economic conditions? There is a general feeling that mental and nervous maladjustments are now more widespread than ever, due to the anxieties, insecurities, fears, the mental stress and strain that naturally spring from unemployment and economic distress. And there is the belief that the seeds of much future mental disorder are being sown during this period of social and economic dislocation and lowered morale. What are the facts?

Inquiries made by mental hygiene agencies do not reveal a general rise in hospital admissions that can be readily interpreted in terms of the depression and there is perhaps little ground for pessimistic or alarming apprehensions in this connection. There is, rather, a feeling that the effects of the depression will not be apparent for some time to come—not until certain factors that usually enter into the precipitation of mental disorders have had time to operate. This is in accord with the understanding of modern psychiatry that mental diseases do not occur suddenly but develop gradually over shorter or longer periods of time.

"The present economic depression," Dr. Pratt states, "is taxing to the utmost man's adaptive possibilities and the difficulties of adjusting to new and painful situations find reflection in an interesting variety of community phenomena. Most, if not all, these phenomena are related to problems of human security. Every individual needs to develop a sense of security if he is to be an efficient community asset. This sense of security is an emotional state which permits one to attack the reality problems with which one is faced with a minimum of dislocated emotion. Such a feeling of security arises largely from the development of adequacies of skills and from a confidence in one's ability to deal capably with a variety of life situations."

To acquire this feeling of security, the announcement points out, man's personality as well as the environment in which he functions must contribute more to a feeling of security than to a feeling of insecurity. Among the most fundamental reality situations that threaten security it mentions those that menace the maintenance of life itself, as in war; great catastrophes; illness; and, for the present, the economic depression. Fear is the spectre that is taking the joy out of our lives at the present time. "Fear enters definitely into the whole picture—constructively at times, destructively at others. Fear becomes destructive when large masses of people are involved in distressing reality situations, such as unemployment and the necessary reduction in standards of living."—*Mental Hygiene Bull.*, 10, 1 (Jan.), 1932.

## PSITTACOSIS

A SEVERE outbreak of psittacosis came to our shores about 3 years ago as an unwelcome visitor. It was the object of many intense studies during which a number of laboratory infections with some deaths took place. We thought that it had been entirely eradicated, and possibly this was true. However, in December, 1931, and January, 1932, 12 cases occurred in the State of California, with 6 deaths. The cases were distributed over 7 counties, though 6 of them took place in 1 county. One fatal case was that of an inspector at the Port of Los Angeles, who had been boarding ships bringing birds from the Orient and the Tropics. His most likely exposure was to a number of parrakeets from one of these ships which he took to his home shortly before falling ill. As they had been destroyed when the facts became known, further investigation was impossible. One other case was due to a pair of parrakeets given as a Christmas gift. The birds appeared well, but laboratory examination proved that they were infected with psittacosis.

In addition, 3 cases, with 1 death, have occurred in New York City. The infection was traced in 1 case to a parrot which been put to board at a pet shop and became ill a few days after being taken home. Another case was an attendant at the same pet shop. It was shown that this shop had received a shipment of parrakeets from San Francisco in September. During October, 12 birds died, and some 40 were

sold. The others were sent to the Rockefeller Institute and psittacosis proved in several. One case has been reported from Oregon, due to parakeets from California.

To date (March 15) there have been 22 cases in California, with 8 deaths. The situation is more serious than would appear from the number of cases. Importation of parakeets might very well and fairly easily be stopped. However, certain sections of California provide ideal surroundings for the breeding and raising of these birds, and it has recently become quite an extensive industry there, in which some 3,000 poor people are concerned, in addition to about 1,500 dealers. If these breeding places in the state have become infected, the situation is complicated. So far the authorities have not been able to make a definite statement because dealers from whom infected birds have been obtained buy their stocks from various sources, and the birds are mixed. Circumstantial evidence points to importation of infected parakeets. Needless to say, strict quarantine has been imposed both on importation into and exportation from the state, until it is certain that the disease has been eradicated. The state authorities can be depended upon to protect the people of California as well as the rest of the country.

## THE DEPRESSION AND PUBLIC HEALTH

ONE of the most serious aspects of the depression is its effect on public health work. From all parts of the United States, as well as Europe, reports are coming in of curtailment of budgets, reduction in personnel, and limiting of projects, such as preventive campaigns against diphtheria, typhoid fever, etc. Many of our state boards are, as it were, living from hand to mouth, with only money enough to keep things going. Any aggressive work and excursion into new fields of prevention are out of the question. Publications are also hard hit, and there is little ground for optimism in sight.

It is futile to quote the great men of the past, statesmen, as well as scientists, to prove what health means to any nation. It required the World War to convince some of the foremost position which public health work should have in social organizations. In spite of this, it now looks as though another lesson is needed. Not that the governments of any state or country will deny the fundamental facts, but they do not seem to have that living faith which compels them to give to public health the position which it should rightfully have. We are not oblivious to the difficulties of the situation, but believe that it has been fully demonstrated in every part of the world that the "care of

the public health is the first duty of the statesman." Apart from physical and mental efficiency, which means good citizenship, there can be little doubt that the work of the Medical Section of the League of Nations has done more to bring about friendship between the nations and to promote peace than any other single agency.

The situation in this country is so serious that the Executive Board of our Association has felt compelled to call the attention of executives throughout the country to the dangers involved. There can be little doubt that the members of our Association, especially those engaged in active work of health administration, or in carrying out field projects, are keenly aware of the bad effects of curtailment of funds. Many of them are in positions to approach directly the appropriating bodies. Many others are not. It behooves our entire membership to exert all influence possible, direct or indirect, to give the public as well as appropriating bodies a clear understanding of what is involved. The following resolutions have been adopted and are being sent over the signature of the President to governors, mayors, Chambers of Commerce, and Federations of women's clubs throughout the United States.

*Resolution of the Executive Board of the  
American Public Health Association, Monday, February 8, 1932,  
on the Present Emergency in the Administration of the Public  
Health Departments of the States, Counties and Cities of the United States*

WHEREAS, the American Public Health Association is receiving from many sections of the country reports of contemplated or actual material curtailments of appropriations for personnel and facilities of public health service in states, counties and cities in response to the general effort towards reductions in governmental costs, and

WHEREAS, up to the present time, the health of the people has been year after year raised to higher levels, and maintained despite the unfavorable economic situation, this being in large part the direct result of the efficient health organizations that have been built up, and

WHEREAS, expenditures for the protection and promotion of the public health have heretofore been minimal, comparing poorly with expenditures for other public services of intrinsic merit, and, therefore, do not lend themselves to deflation without jeopardizing the health of the people, be it

RESOLVED by the Executive Board of the American Public Health Association, that every effort be made to maintain and even to advance the effectiveness of our health departments, and that the various agencies in the communities interested in the public health be asked to maintain unimpaired health budgets, trained personnel and services which have proved their worth in safeguarding the first wealth of every community—the health of its people.

For the Executive Board,

LOUIS I. DUBLIN, *President*

## TRANSMISSION OF MOSQUITOES BY AIRPLANES

IT is an axiom that human disease travels no faster than means of human communication. With the increased speed of communication due to steamships versus sailing vessels, express trains, and most recent of all, airplanes, the spread of disease has become easier, and it is a trite saying that we are now in close touch with every part of the known world—a matter of days and hours, when formerly it was months and weeks.

The discussion of the transmission of disease by airplane by the Permanent Committee of the International Office of Public Hygiene, was mentioned in our columns.<sup>1</sup> It was again an object of discussion at the meeting in Paris, May, 1931. It was recognized that though the conditions existing in the various countries were widely diverse, the provisions adopted corresponded to the general needs essential to sanitary defense and were a guarantee against any arbitrary action concerning international air relations, though that would not exclude legitimate intervention in times of immediate danger. The danger of infected people traveling by airplane has been lessened by detention and observation before embarkation, but there still remains the possibility of carrying infected insects, particularly mosquitoes. We are in close communication with the West Indies, the west coast of South America, Central America, Cuba, Panama, Mexico, and Jamaica, and there are three regular lines, daily and triweekly, between Miami, Fla., and the countries to the south of us, some of which were formerly heavily infected with yellow fever, and practically all of which harbor the yellow fever mosquito.

In view of the present situation and the certainty of increased airplane traffic in the future, officers of the U. S. Public Health Service have carried out a series of experiments on the transmission of mosquitoes by airplane.<sup>2</sup> From September 12 to September 18, 1931, more than a hundred inspections of planes from the southern countries were made on arrival at Miami. Twenty-nine mosquitoes were captured, the majority of which were non-disease-bearing, though several times *Aedes aegypti* were found, and once an *Anopheles*, showing that under natural conditions mosquitoes are carried considerable distances in planes.

To study the matter further, captured mosquitoes were stained with eosin and released in planes just before leaving.<sup>3</sup> Of 40 mosquitoes, nearly all *Aedes aegypti*, released in the cabin of a Fokker at San Juan, 13 were recovered in Miami, the distance traveled being 1,250 miles and time 9 hours and 53 minutes. In a second experiment, of 30 stained mosquitoes, 3 were captured on arrival at Miami,

and one was active during the trip, biting the radio operator when at an elevation of 3,000 feet. In a third experiment the pilot was bitten while in flight, and 6 mosquitoes were recovered at Miami. Altogether, in 3 experiments some 100 stained mosquitoes were released in the cabins of airplanes, and 22 of these were recovered in Miami, the distance traveled being 1,250 miles and the average time of the trip 10 hours and 10 minutes. There can therefore be no doubt of the potential danger of the carrying of infected mosquitoes by airplanes. However, planes may be freed from mosquitoes at points of departure by simple spraying, and the writers of the article quoted believe that there is no obstacle to the efficient treatment of airplanes for the destruction of mosquitoes and thus avoid the retardation of air traffic.

## LETTER FROM GREAT BRITAIN

### CONGRESS OF THE ROYAL SANITARY INSTITUTE

THE invitations to local health authorities and other bodies to appoint delegates to attend the annual congress of the Royal Sanitary Institute, at Brighton from July 9 to 16, have now been issued, and the effect on the attendance that may result from the present stringency is causing some anxiety in certain minds. Almost invariably it is the practice of authorities sending representatives to make themselves responsible for the payment of expenses, and in places where accounts are subject to government audit, the payments are permitted, provided the Minister of Health agrees.

In ordinary years the Minister permits the Institute to announce, in the invitation to attend, that he is prepared to approve the expenditure of one or two delegates, and at the audit no further evidence of approval than this is required. On the present occasion,

permission to appoint delegates and pay their expenses has not been given generally, but must be sought by each authority individually and must be supported by reasons for desiring to make the appointment.

From the form of the wording of a letter on the subject from the Ministry it is believed that permission is not likely to be withheld in any case, and that the Minister and his department generally are as anxious as health authorities and their officers to insure the success of the meeting, and that as many as possible of those engaged in health work shall have the opportunity of getting together and discussing health problems and the effect upon them of present conditions.

Brighton, the venue of the meeting, is a famous health resort and a great convention center. The local council is one of the most progressive health authorities in the country, and for this, among other reasons, will be seriously

disappointed if the meeting is not a magnificent success, attracting delegates not only from Great Britain but from overseas and from other countries. The average attendance at the congresses is about 1,400 or 1,500, and the Council of the Institute naturally hope that this figure, at any rate, will be reached. As President of the Institute, that body has recently elected Lord Balfour of Burleigh, who has devoted great attention to municipal government on the public health side particularly. The family name of Lord Balfour, it may be of interest to note, is Bruce, and he claims descent from Robert the Bruce, the Scottish monarch, whose observations on the habits of the spider are still quoted with approval in books treating of the history of Scotland.

#### SALARY CUTS IN THE HEALTH SERVICE

The possibility exists, of course, that some authorities may refuse to send representatives to the congress in order to use it as one of the means of securing some part of economy to be credited to the works done in relation to public health. The amount would, naturally, be trivial but speaking generally the economies that can be made in health expenditure cannot amount to much. They are, indeed, so small as to be hardly worth troubling about, more particularly as the effects they produce are out of all proportion to the money saved.

This, as a fact, is true of many of the economies suggested or adopted by local government bodies. Particularly is it true of the salary cut method. This, which was recommended as a gesture by the Ministry of Health, appealed very strongly to a number of authorities, who saw that it was put into operation almost immediately. At present about half the areas in the country are affected. In the places in which it is not in operation those who favor it urge its adoption in the face of

evidence that the deductions made are totally inadequate to bring benefit to anybody or to do more than cause irritation and inconvenience and hardship to those who must suffer them. So far as the public health service is concerned—or certain sections of it, anyhow, the medical officer of health and the sanitary inspector in particular—the position is peculiar. Having security of tenure these officers can only have their salary reduced if they consent. If they refuse they are at liberty to resign. They may not be discharged without good cause and subject to the consent of the Minister of Health. No difficulties have arisen over discharges up to the present and it is doubtful if they will, since no authority probably will take the risk of discharging a health officer for failing to offer or refusing to accept a salary cut, much as some of them would like to do so.

#### LONDON AND ITS FOGS

Though at the back of his mind he appreciates the seriousness of fogs from the health and economic point of view, the Londoner is always ready to jest about them and to laugh at rather than resent the action of the American film producer who, when he must show London, inclines to represent it in a state of more or less complete darkness.

One of the reasons why the Londoner has laughed, recently at any rate, has been because of a conviction that things have been improving to such an extent that presently the "London particular" would be a thing of the past. How wrong he has been and how justified the film producer, is shown in the report of the Department of Science and Industrial Research on observations made during the year ended March 31, 1931, in connection with the investigation of atmospheric pollution that has been going on for the last 17 or 18 years. The observations upon which the report is based were carried out in a

large number of centers throughout the country, and in practically every instance the results show that considerable improvement has taken place, the amount of impurity deposited being greatly reduced.

From the records it does not appear that London has shared at all in the general improvement. The unfortunate Londoner, indeed, is warned that from all appearances "as regards impurity suspended in the atmosphere, it seems probable that London may have to put up with black fogs for many years to come." And to make matters worse, he is told by the reporters that they cannot understand where "the general optimistic belief in the reduction of smoke fogs" has come from.

Even after such knock-down blows it is improbable that the Londoner will abandon his optimism. In spite of his coughing ("Britons," said the American writer, "never, never shall be slaves—except to their catarrh"), and in spite of investigators, he will aver that there are fewer fogs and they are nothing like what they were when he was a boy. "And in any case," he will add, "there is always May; and in London in May, fogs are soon forgotten."

DR. PARLANE KINLOCH, SCOTTISH  
DEPARTMENT OF HEALTH

By the death of Dr. Parlane Kinloch,  
Principal Medical Officer of the Scottish

Department of Health, preventive medicine over a much wider area than Scotland has suffered a very serious loss. It is all the more serious because at the time of his death he was only 46 years of age, and was definitely in process of establishing himself as one of the outstanding figures of his decade.

The great bulk of his work had been done in Aberdeen, and it was because it showed so much of initiative, originality and enterprise that when the time came to appoint a successor to Sir Leslie Mackenzie, those responsible wasted no time in looking beyond Kinloch. As the health worker must be, he was very much of an idealist, but in his idealism there was a wide streak of the practical which showed particularly in the scheme that he had formulated and that he saw adopted, to an extent, of amalgamating all the health activities of an area and so getting rid of overlappings liable to lead to friction.

It had been hoped that he would have been able to form part of the delegation of British health officers at the Montreal meeting of the American Public Health Association, but greatly to his regret he had to refuse the invitation. This was very unfortunate, since though he was not counted an attractive speaker, he had a great sincerity and chose always subjects that were original, interesting, and stimulating.

London                      CHARLES PORTER, M.D.

# PUBLIC HEALTH ADMINISTRATION

## FIVE YEARS AT BELLEVUE-YORKVILLE

### AN EXPERIMENT IN HEALTH CENTER ADMINISTRATION

SAVEL ZIMAND

*Administrative Director, Bellevue-Yorkville Health Demonstration,  
New York, N. Y.*

THE Bellevue-Yorkville Health Demonstration, under the leadership of Shirley W. Wynne, Health Commissioner of New York City, completed 5 full years of active operation at the close of 1931.\* During this 5-year period under the leadership of the Department of Health and in coöperation with various official and private agencies, the Demonstration, financed by the Milbank Memorial Fund, has combined an experiment in metropolitan health administrative practices with service for the people of the district at the Bellevue-Yorkville Health Center, and the experience there has been an important factor in the formation of plans to erect other health centers, until every district in the city shall have its center. In addition, many specific services, experimentally inaugurated by the Department of Health with the aid of the Demonstration, have since been installed elsewhere in New York, while others are incorporated in the health program of the city.

Thus certain preventive and diagnostic medical services now regarded as indispensable in the maintenance of a

standard of community health had their preliminary trial in Bellevue-Yorkville in the course of these 5 years. The department's first clinic for preschool children was opened at the Health Center in 1927; since that time two have been established in other districts, and last year two others were opened in the Demonstration area. The school children's clinic and the city-wide diagnostic cardiac clinic for children applying for permits to work (the latter with the assistance of the New York Tuberculosis and Health Association), both at the Health Center, are the first of their kind to be carried on under the auspices of the department. The electrocardiogram for the cardiac clinic was purchased by the Demonstration. The department's first complete mental hygiene unit was established in November, 1930, at the center.

The first Department of Health consultation chest service for private physicians was set up in 1929 at the Health Center; the department now operates five others in various districts of the city. X-ray equipment for chest examination was installed here by the Demonstration and subsequently has been incorporated by the Department of Health in its tuberculosis clinics elsewhere in the city. A pneumothorax refill service, established experimentally at the Health Center in 1931, is the

\* Since its inception, Dr. Wynne has participated actively in the work of the Demonstration, and its most important and successful projects have been started at his initiative and suggestion. Dr. Wynne is now, and has been for the past 3½ years, chairman of the governing boards of the Demonstration, and before that time was its vice-chairman.

first department service of its kind. The extension of this service to other parts of the city is contemplated. The services of a tuberculosis consultant, and of a nose and throat specialist, as well as other medical and clerical staff and equipment, were added by the Demonstration to the clinical services of the department.

Another important contribution of the Demonstration is the assistance given to the department's nursing service. Additional field nurses for the district and clerical help for the nursing service were supplied by the Demonstration in order to provide a more adequate staff, and these gradually have been replaced by the department's Bureau of Nursing. In 1928, 10 additional department field nurses were on the Demonstration's payroll; in 1929 there were 5; in 1930, 3 or 4; and by April, 1931, all had been replaced by the department.

Consultants have been retained from time to time to give advice and assistance in their specialties to the nurses and in the clinics. In addition to those serving in 1931 in the fields of mental hygiene, nutrition, and social service, a recreation consultant, from 1927 to the spring of 1930, assisted in developing play facilities in the district and stimulated interest in outdoor activities among adults as well as children.

Important assistance was given by the Demonstration to the Department of Health in the development of its Bureau of Nursing. Early in 1928, when this was created as a separate bureau, the assistant executive officer of the Demonstration became director of the bureau. The Demonstration later provided, for a limited time, 4 special supervisors. Two of these helped prepare a manual and an educational program for the nurses, a third helped reorganize the system of records, and the fourth was assigned to an experiment in the Bellevue-Yorkville District.

This was the introduction of the generalized system, first applied to nurses of the Yorkville unit in 1929, and then to the Bellevue group, which the Bureau of Nursing now plans to extend to other districts.

An interesting and largely successful experiment in health education in the schools was carried on in coöperation with the Board of Education and the Catholic School Board from 1927 to 1930. One consultant was named for the public schools of the area, another for the parochial schools, and a third served 1 year in a junior high school. Their purpose was to help develop a more complete health education program, and much that was introduced during that period became integral to the program, not only of schools in Bellevue-Yorkville, but of those in the city as a whole. Reports describing these projects are soon to be published.

Health education, applying not exclusively to the school population, but to adults working or living in the district, as well as children, has been directed toward securing desirable changes in public opinion, attitudes, and habits on questions of preventive medicine and public health. Perhaps never before in New York City has such intensive, continuous, and widespread health education work been conducted in a district of 150,000 people. Through picture newspapers, through artistic posters for store windows, schools, and social agencies, through special pamphlets and leaflets, circular letters, motion pictures and open forum meetings, vigorous campaigns were conducted on various aspects of public health—child hygiene in general, vaccination against smallpox, immunization against diphtheria, early discovery of tuberculosis and other preventable diseases, correction of dental and other physical defects. One of the first intensive periodic health examination campaigns in New York City was carried on in the Bellevue-Yorkville

District by the Demonstration in co-operation with the medical profession. Two large-scale campaigns conducted on a demonstration basis dealt with venereal diseases and safety. They overstretched local boundaries in interest, having been the subject of wide newspaper and magazine comment.

The health education work of the Demonstration has had the threefold effect of arousing interest in measures to conserve health, of inducing persons to use the services of private physicians or clinics, and of interesting health and welfare agencies of the district, and in some cases outside its boundaries, to do similar work.

Although this brief summary does not aim to measure statistically the results of the activities carried on by the Demonstration, nevertheless some statistical indications may be recorded. However, it is important to recall that the health work in Bellevue-Yorkville has been carried on in coöperation with a number of official and unofficial agencies, and all of these have had an important part in whatever gains the statistics may show.

A concrete result of the continuous emphasis in the health education program on the need for toxoid inoculation is illustrated by a reduction in the death and case rate of diphtheria. The diphtheria death rate for the district averaged 14.2 per 100,000 during the 5-year period 1922-1926 prior to the opening of the Demonstration, and it was reduced to 8.2 for the 5-year period 1927-1931. The case rate was reduced from 197.3 to 169.5. Even allowing for the cyclical changes of the disease, the case and death rate of diphtheria is below what might be expected. It is striking to note that from August, 1929, to March, 1931, there was not a single death from diphtheria in the district.

Another important contribution to the future health of the city is the ad-

vance in child hygiene made in the district in the past 5 years. Through the efforts of a competent and informed nursing service, and as a result of systematic health education, a considerable proportion of the infant population is under observation either by private physicians or in the baby health stations. Approximately 50 per cent of the babies born in the area during 1931 were registered in the three baby health stations. Consultation of private physicians was, of course, persistently urged in every connection.

The infant mortality rate in Bellevue-Yorkville averaged 93 per 1,000 births during the 5-year period prior to the opening of the Demonstration, and was reduced to 86 in the period 1927-1931. The last 3 years have shown a marked decrease, and the rate for 1929-1931 was only 79. The tuberculosis death rate in Bellevue-Yorkville was reduced from 148 per 100,000 during the period 1922-1926 to 116 in the period 1927-1931; while the rate in Manhattan was reduced from an average of 130 in the years 1922-1926 to 123 in the years 1927-1931, and in New York City as a whole from 94 to 74.

During the same period (1922-1926 and 1927-1931) improvements also took place in Bellevue-Yorkville in the death rates of typhoid fever (from 4 to 1 per 100,000), measles (from 17 to 2), scarlet fever (from 3 to 1), whooping cough (from 7 to 3), diarrhea and enteritis (from 40 to 26), and pneumonia (from 212 to 210). The only death rates in this period which show an increase in Bellevue-Yorkville are those of the so-called degenerative diseases (cancer, cerebral hemorrhage and diseases of arteries, and heart disease) and from accidental causes.

But it should be pointed out that the population of the district is so fluctuating not only in numbers, but in its very character, and the influences affecting the death rate and the prevalence of

disease are so powerful and far-reaching, that without far more detailed information than we have at present, and more careful study, it would be impossible to test the usefulness of the work by means of statistics alone.

Two research studies of major importance have been made by the Demonstration. The first was a comparative and clinical investigation of vulvovaginitis, undertaken to provide a basis for advising a practical method of diagnosing gonorrheal vaginitis and to determine the relative efficacy of the several methods of treatment. It was done with the assistance of the Willard Parker Hospital. Begun in 1927, and concluded in 1930, this study is summarized in a report soon to be published, giving a description of clinical procedure and an account of bacteriological work. The report includes the social facts as well as the medical histories of the 322 patients from all parts of the city who were observed.

A study of tuberculosis in 1,000 school children of 13 and 14 years was carried on in 1930. This, it is felt, added to the available information regarding diagnosis and prevalence of this disease in the age group studied and served as a trial of methods which might prove practical in other parts of the city.

The dental service at the center maintained, since 1927, jointly by the Tuberculosis Committee of the Association for Improving the Condition of the Poor, and the Demonstration, has carried on both a clinical and an educational program. The efforts of the service were combined with those of the schools, dental societies, and other community agencies. The educational part of this work cannot be measured statistically, but the following figures give some indication of what has been accomplished in the clinic. In the 5 years from its establishment in 1927 to the end of 1931, the number of pa-

tients treated (nearly all school children) was 11,502. The total number of operations performed was 68,108, an average of 5.9 per patient.

Of recognized value too is the quarterly and yearly compilation, prepared by the Demonstration's division of records, of vital statistics for the 25 sanitary areas comprising its district. A record of the prevalence of diseases, so localized, has made possible greater efficiency in the direction of preventive activities by the Health Center. The Committee on Neighborhood Health Development of the Department of Health, in preparing data for city-wide activities, has been guided to a great extent by the practical experience in Bellevue-Yorkville.

After due trial, certain experiments were discontinued as impracticable on a city-wide scale, or for various specific reasons. An evening Department of Health venereal disease clinic, established in 1927 and closed in 1929, gave 1,703 treatments to 384 patients. The expenditure for the equipment and social service was provided by the Demonstration. Intended primarily as a diagnostic service for physicians, this was, as a matter of fact, sought less for that purpose than for treatment. During 1928 and part of the following year, the Demonstration provided clerical and social service assistance to three venereal disease clinics in the Bellevue-Yorkville District. This was apparently a real help in improving their records and routine and in demonstrating to those directly responsible the need for additional facilities and staff.

For a trial period of 6 months in 1930, office nurses were provided free of charge to give part-time service to private physicians. After the experimental period, those who wished to continue were to pay for the service. To facilitate the private practice of preventive medicine, an arrangement was made in the same year whereby the Demon-

stration met the expense of laboratory tests, such as were not already provided free by the Department of Health, needed by patients unable to pay the usual fees. While both of these trial services awakened real interest, this was not thought to be wide enough to warrant continuing them. A graduate course in the technic of making general health examinations was given for physicians of the district for several terms in 1928 and 1929, but it was not continued thereafter, for it proved to be an expensive method of providing a limited amount of instruction.

Throughout this period, the Bellevue-Yorkville Health Demonstration has been most fortunate in the coöperation it has enjoyed from official and unofficial agencies, especially the Departments of Health, Education, and Police, the Catholic School Board, the churches, voluntary health and welfare organizations, dentists and dental societies, and the medical profession. In all its major efforts this coöperation has been a very important factor. Private physicians in the district have worked with the Health Center in many important projects, and physicians elsewhere in the city have given valued support. Since the opening of the Demonstration, the president of the County Medical Society has served on the Community Health Council.

While new aims have developed in the course of 5 years, the original aims have in the main controlled the program of the Health Demonstration. Known facts about the prevention of disease have been applied to a given area, with the implication that a test of the success of the health program is that it must be applicable to the city as a whole and to other urban areas. At the same time, some services of the Demonstration have overstepped the boundaries of the area, and new city-wide services have been added.

The number of new patients regis-

tered, and the total number of visits these patients made to the various clinics in the past 5 years, indicate roughly the extent and range of medical services performed. It is important to consider the total attendance, since most patients made repeated visits for reëxamination, or immunization, or for advice and consultation. Since 1927, the three baby health stations now functioning, and a fourth which operated only during 1927 and 1928, have enrolled 4,670 new patients, and had a total attendance of 94,507; the preschool clinic established the end of 1927 and the two added in the summer of 1931 enrolled 1,687 children, and had a total attendance of 10,235; and the school children's clinic, since its organization in 1928, has had 1,273 boys and girls upon its register with a total attendance of 2,984.

In the tuberculosis service, the Yorkville district chest clinic for adults and children has examined 4,614 new patients in 5 years, and had a total attendance of 13,634, a large percentage of which were reëxaminations, while the consultation chest service for private physicians has examined 3,294 new patients in the 3 years of its existence, with a total attendance of 4,807. It should be added that every effort has been made to bring in the tuberculosis contact cases, and as a result 78 per cent of the contacts were examined in the years 1930 and 1931.

The consultation chest service for private physicians is designed for those who can afford to pay the fee of their physician but who are unable to meet the cost of X-ray diagnosis and a specialist's examination. Complete findings and an opinion on the case are forwarded to the patient's physician, and no information or advice is given directly to the patient. At the Yorkville district chest clinic, the patient applies directly for diagnosis, advice, and placement. The attending medical service of the clinic has been so reor-

ganized that the patient can always have the same physician and be looked after by the same nurse. It is felt that this method has strengthened the contact between patient and doctor. The children's service of the Yorkville district chest clinic was reorganized in October, 1930, and has proved an important source of discovering new cases needing attention.

Well babies are admitted for examination, immunization, and advice to one or another of the Department of Health baby stations located in the district. At the preschool clinics the same procedure is followed. Correction of physical defects before children are old enough to enter school is encouraged, and arrangements for attending to this may be made with special clinics. Children of school age who require more complete or more detailed physical examination than can be given by school examiners are admitted for diagnosis and observation to the children's clinic, located at the Health Center, especially designed for this purpose. Thus the work of the Department of Health doctors in the schools is supplemented, and the clinic also serves as a clearing house for referring certain children to the special clinics.

At the cardiac diagnostic clinic, which was started as a result of the work of the Cardiac Committee of the New York Tuberculosis and Health Association, a thorough examination is given to every child suspected of having a cardiac condition, among those applying for working papers. The cardiac study includes an electro-cardiogram, teleo-roentgenogram, urinalysis, and complete physical examination. As a result of the work of this clinic, some children were prevented from taking up work which would have been harmful to

their health, while others were relieved of the fear of cardiac conditions and sent back to normal occupations. The objectives of the mental hygiene unit are to carry out among the Bellevue-Yorkville Department of Health nurses an educational mental hygiene program, and to be of service to patients referred by them or by doctors in the various clinics of the department. An important contribution of this service is the progress that has been obtained in working with and through the Department of Health nurses and the medical members of the various clinics.

Such in the main have been the activities of the Demonstration during the past 5 years.\* Some of the achievements can be measured in black and white figures. But there are other more intangible aspirations to which it clings. Who, for example, is able to measure statistically the value of an opportunity for health, with its resultant opportunity for happiness? In seeking to bring this health opportunity within the reach of the less fortunate in the broad and varied territory of the Bellevue-Yorkville District, the Demonstration opens ever widening vistas. Nor are the effects of these activities confined entirely to the district. As pointed out above, some of the work has borne fruit throughout the city, and the ultimate influence of these efforts may be far greater than we at present can conceive.

---

\* The years 1922, 1923, and 1924, the so-called prenatal period of the Demonstration, were given over largely to studies on which the choice of a location and the general plan of organization were based. The years 1925 and 1926, the organization years, were spent largely in making further statistical studies of conditions in the district, planning programs, remodeling and furnishing the Health Center, which was opened on August 31, 1926, etc. The population of the district, which extends from 14th to 64th Street on the east side of Manhattan, with Fourth Avenue as the western boundary below 42d Street and Sixth Avenue above, was reduced from 175,000 in 1925 to about 146,000 in 1931.

Madison, Wis.—This city with a population of 57,899 in 1930 operated on a health department budget of \$34,598, exclusive of hospitalization. A general death rate of 8.8, a birth rate of 19.3, and an infant mortality rate of 44.8 are noted. Of 41 cases of diphtheria reported, only 2 were considered as chargeable to the city, as 28 were non-residents and 11 occurred among nurses and employees of the hospital in which the majority of non-resident cases were treated. No diphtheria occurred among nurses or employees of the quarantine hospital. There were 8 cases of typhoid fever, 5 in one family, all non-residents, who were brought to the hospital for treatment.

The Board of Health maintains an eye, ear, nose, and throat clinic, to examine, advise, and correct defects among school children. The children who are sent to the clinic have had a preliminary vision test by their teacher and a public health nurse. If a child is found to have defects, a notice is sent to the parent with advice regarding correction. The indigent cases are returned to the clinic for complete examination and treatment. Glasses are furnished if necessary, and operations for removal of tonsils and adenoids are performed at the hospital at the expense of the Board of Health.—*Annual Report*, Madison Board of Health, 1930.

**Vital Statistics for Montreal, Canada, 1930**—The annual report of the Montreal Department of Health for 1930 maintains the standard of excellence set by the department in its annual reports, which present a clear

statement of health conditions in Montreal and the activities of the department.

It is interesting to note that the estimates of population made by the department are confirmed by this year's census figures. The birth-rate of 26 is below the average, which was 31 for the past 10 years. The same is true of marriages, which were 8.4 per 1,000, as compared with an average of 9.4 for the preceding 10 years.

The general death rate of 12.9 per 1,000, shown in this report, is the lowest rate experienced by Montreal. It represents a decided gain over the rate of 15.2, the average of the past 10 years. An infant mortality rate of 124 is high, but it is low as compared with the records of past years. Diarrhea and enteritis are responsible for one-third of these deaths, and this indicates the need for more instruction in infant care. The mortality from tuberculosis continues to decline from a ten-year average of 143 deaths per 100,000 to 124 in 1930.

The rates vary considerably for the different races making up the population of Montreal. The French-Canadian birth rate is 31.9, and their infant mortality rate, 136. The British-Canadian rates are 17.8 and 78 respectively.

Deaths from cancer and organic disease of the heart are increasing; deaths from pneumonia and broncho-pneumonia are decreasing. The cancer rate for the first time went over 100, being 102; the average for the past 10 years was 84.—*Canad. M. A. J.*, 25: 755 (Dec.), 1931.

# LABORATORY

## THE ISOLATION OF AN ORGANISM OF THE ABORTUS-MELITENSIS GROUP FROM A BLOOD CLOT, THE SERUM OF WHICH FAILED TO GIVE AGGLUTINATION WITH *B. ABORTUS*\*

RUTH GILBERT, M. D., F. A. P. H. A., AND H. GLADYS DACEY

*Division of Laboratories and Research, New York State Department of Health,  
Branch Laboratory, New York, N. Y.*

AN organism of the abortus-melitensis group was isolated from a specimen of clotted blood submitted to the laboratory 3 weeks after the onset of illness. No agglutination of *B. abortus* was obtained either in this specimen or in one examined 2 weeks later. No agglutination of *B. typhosus*, *B. paratyphosus* A, or *B. paratyphosus* B was obtained. The clot was cultured in a bottle of liver-infusion broth which was stoppered with a rubber stopper and incubated at 37° C. for 1 week.

Subcultures were made on liver-infusion agar at the end of this time and incubated in a closed jar in which approximately 10 per cent of the air had been replaced by carbon dioxide.

After 1 week's incubation, colonies of organisms belonging to the

abortus-melitensis group had developed.

Suspensions of the growth were agglutinated in a 1:2,500 dilution of immune serum prepared with *B. abortus*. The organisms were not agglutinated in the patient's serum.

The patient, a housewife of 45 years, became ill on April 1, 1930, with a pain in the chest, headache, vomiting, shortness of breath and fever varying from 100° to 103°. Remissions of temperature occurred every day at noon and lasted for 4 hours. In April, 1928 (two years before), the patient had been ill for 18 weeks with exactly the same symptoms.

There was no history of contact with goats, cows, or swine, but the patient had consumed raw cow's milk from a herd in which abortions had occurred.

## A MODIFICATION OF THE FILDES ANAEROBIC JAR

G. D. CUMMINGS

*Bureau of Laboratories, Michigan Department of Health, Lansing, Mich.*

MCINTOSH and Fildes<sup>1</sup> published specifications and directions in 1916 for the operation of an anaerobic jar utilizing the palladium capsule for combining hydrogen and oxygen. Fildes<sup>2</sup> further improved the method in 1921. In the same year Brown<sup>3</sup> pub-

lished further modifications of the Fildes jar.

All three papers specified the use of a glass museum jar covered by a metal top. The modification here presented is the same in all fundamentals as in the methods of Brown and Fildes with

three exceptions—the construction of the jar, the resistance unit, and the gasket seat. For early experiments the writer used the method as advised by Fildes, that is, glass jar, metal top with platinum coil suspended below, and light bulb resistance. During the 21st run, the apparatus exploded and was completely demolished. This experience was sufficient to cause the writer to have a metal jar constructed to take the place of the glass one.

The specifications are as follows:

1. Jar (See Figure I)—The jar was constructed from a piece of brass pipe 6" outside diameter x  $9\frac{3}{8}$ " long x  $\frac{3}{16}$ " thick. A brass bottom was soldered on and sealed both inside and out. A brass collar holding three eyebolts with wing nuts and washers was slipped on over the top of the jar and screwed into place. The collar was sealed with solder to insure an air tight fit.

2. Cover (See Figure II)—The cover was cast in brass in one piece and notched at points to correspond to the wing nuts attached to the collar of the jar. Four holes were drilled through the top, two for binding posts and two for the inlet and outlet valves. These joints were made tight by painting all screw threads with a combination of graphite and shellac. A copper tube was attached to the under side of the inlet valve leading to the bottom of the jar. The under side of the cover was reamed out to fit a rubber gasket,  $5\frac{7}{8}$ " inside diameter x  $\frac{1}{2}$ " wide, thus cutting down the possibility of gasket spreading and subsequent passage of air into the jar. This point is important, as a flattening of the gasket and air suction into the jar apparently caused the above mentioned explosion. The palladium coil, surrounded by fine mesh brass wire, was suspended from the under side of the cover by two hooks screwed into the cover. The portions of the coil, hooks, and inlet pipe, shown in white in the above figures, were covered with adhesive tape to prevent contact of the coil wire with the metal of the jar.

3. Palladium coil (See Figure II)—The coil was constructed as in the Fildes specifications. 0.25 gm. of asbestos wool were soaked in 1.5 c.c. 10 per cent palladium chloride and the asbestos molded into a small square in an evaporating dish. The mass was gently heated until almost dry and then wrapped around a  $\frac{1}{4}$ " glass rod with lens paper. A No. 8 rubber stopper (large end out) was

FIGURE I

placed on either end of the rod and a 20 G needle was passed through each. The needles were cut at both ends, thus allowing easy passage for the resistance wire; 2.41 ft. (50 ohms) of 35 G B & S nichrome wire were tightly wound around the asbestos, and the ends passed through the needles in the rubber stoppers. The wire was wound on tightly enough to allow sufficient length on the outside of each stopper for attachment to the under side of the respective binding posts. The coil was heated in a smoky flame, ignited, and finally wrapped in the brass-mesh wire and taped into place. (At this point the coil should ignite a stream of hydrogen.) The coil was suspended on the hooks and the ends of the resistance wire attached to the binding posts.

4. Resistance (See Figure II)—For resistance 2.89 ft. (60 ohms) of 35 G B & S nichrome wire were used instead of light bulbs on a 110 volt circuit. The porcelain coil

FIGURE II

shown could be much smaller but was the only one available at the time.

5. Hydrogen source (See Figure I)—Technical grade zinc and technical hydrochloric acid were used as the hydrogen source. This source was used deliberately rather than tank hydrogen to assure drop by drop control.

6. Operation—Clamp on top and attach hydrogen generator (See Figure I)—With both valves open, allow a slow but steady stream of hydrogen to pass into the jar for 2 minutes. Shut off hydrogen supply, close both valves, and plug jar and resistance into light circuit for 20 to 30 minutes. During this time the top should heat up so that the change in temperature becomes easily detectable. During the whole operation the connection between the hydrogen generator and the jar should not be broken. Open inlet valve and the vacuum created in jar will be indicated by suction on the acid in the tip of the separatory funnel. Run hydrogen slowly into jar until it will take no more. With the inlet valve open repeat this procedure at intervals of 2 to 3 minutes until the jar will finally take no more hydrogen (total time less than 10 minutes). Close off inlet valve, disconnect resistance and hydrogen generators and incubate the jar.

This jar incorporates the following changes from the Fildes and Brown methods: (a) All metal jar; (b) stand-

ard resistance supplied by nichrome wire; and (c) inset gasket in metal cover. The metal jar eliminates the possibility of explosion and allows the use of a well heated palladium coil, the securely seated gasket eliminates air leakage, and the nichrome wire throughout allows a constant number of ohms resistance in the palladium coil and in the resistance unit. The main disadvantage is that the operator is unable to see what growth takes place or to observe whether the methylene blue control tube stays colorless. After several runs, however, the operator is able to predict the efficiency of the jar by the amount of acid taken up in the formation of hydrogen, and to predict the action of the methylene blue tube.

To date the writer has isolated 14 strains of *Cl. tetani* from soils and manure using the Fildes technic and has cultivated stock strains of the organism with extreme ease.

# VITAL STATISTICS

**Vital Statistics in Indiana, 1931—**  
The Vital Statistics Division of the Indiana State Board of Health has published a tentative report for the calendar year 1931. According to this report, the state enjoyed last year the lowest general mortality in its history. The death rate from all causes was 11.9 per 1,000 population, as compared with 12.1 in 1930. The birth rate in 1931 was 17.2 as contrasted with a rate of 18.3 in 1930 and 21.6 in 1922.

It is interesting to note that the death rates from tuberculosis (61.1), typhoid fever (2.9), infant diarrhea (13.9), puerperal septicemia (2.6), and from all puerperal causes (9.6) are the lowest from these causes that have ever been recorded in Indiana. Contrasting these rates with the figures shown for 1922, it is noticeable that a great improvement has taken place. Tuberculosis showed a death rate of 88.1 in 1922, the 10-year period 1922-1931 indicating that a reduction of 31 per cent in the death rate from this disease has been effected. In the same period, the typhoid fever death rate has been reduced 63 per cent, infant diarrhea 43 per cent, puerperal septicemia 55 per cent, and all puerperal causes 28 per cent. Diphtheria which showed no reduction in mortality from 1930 to 1931, has, however, dropped from 18.2 in 1922 to 4.1 in 1930 and 1931, a reduction of 77 per cent. Similarly, the infant death rate was not lowered in 1931, the 1930 rate of 57.4 holding in 1931 also. This rate compared with the 1922 rate of 68.1 means a considerable saving of infant lives during the last decade.

There was a noticeable increase in the death rate from cancer (106.1 as compared with 104.6 in 1930 and 94.5

in 1922). This increase in death rate amounts to a 12 per cent increase during the last decade. Deaths from external causes increased from 3,522 in 1930 to 3,660 in 1931, giving death rates of 108.7 and 112.7 for the years 1930 and 1931 respectively. In spite of these increases in cancer and accidental deaths, it is encouraging to note a substantial reduction in the death rate from organic heart disease, from 190.0 in 1930 to 176.8 in 1931, even though this 1931 figure does not compare favorably with the death rate of 156.8 recorded in 1922.

Beside the above mentioned changes in mortality from 1930 to 1931, the report for Indiana showed increases in the mortality from scarlet fever, measles, whooping cough, influenza, suicide, and automobile accidents; while decreases were observed in the mortality from pneumonia, acute poliomyelitis, cerebrospinal meningitis, homicide, smallpox, apoplexy, and Bright's disease.—*Month. Bull.*, Indiana State Board of Health, 35: 2-3 (Jan.), 1932.

**Health in New York City, 1931—**  
The New York City commissioner of health, in his annual report submitted December 31, 1931, records the lowest infant death rate (56 per 1,000 births) and the fewest deaths from diphtheria (185) in the history of New York City. Despite the severe economic depression and unusual outbreaks of influenza and poliomyelitis, the general death rate of 10.92 compared favorably with that of 10.76 in 1930 and 11.34 in 1929. The total number of deaths in 1931 was 77,418. There were 954 deaths from influenza in 1931, as compared with 483 in 1930; the outbreak resulted in

about 2,000 deaths above the normal expectancy, however, when deaths registered under pneumonia and other causes, in which influenza played a part, were considered. During the poliomyelitis outbreak, 4,087 cases were reported to the department and there were 490 deaths. In the outbreak of 1916 there were 9,023 cases, with 2,448 deaths.

The year was also marked by a high prevalence of measles, 26,516 cases having been reported; whereas in 1929 there were only 2,500 cases. Deaths from automobile accidents were more numerous than deaths from typhoid fever, measles, scarlet fever, diphtheria, whooping cough, cerebrospinal meningitis, and deaths of mothers in childbirth, combined. There were 1,302 deaths in 1931, an increase of 26 over 1930. Deaths from diabetes amounted to 1,921 as against 1,784 in 1930. Cancer increased from 8,125 in 1930 to 8,333 in 1931. The city's birth rate was 16.31, the lowest ever recorded.—*J. A. M. A.*, 98: 239 (Jan. 16), 1932.

**The Geography of Homicide—**Geography is an important factor in homicide. Race likewise has a big influence over the murder rate. Density of population and the existence of large cities in the territory seem to have very little to do with homicide. These conclusions appear to be justifiable on the basis of statistics compiled by Dr. R. N. Whitfield, State Registrar of vital statistics in Mississippi, who collected data from all but 6 states in the United States and from Canada for the 3 years of 1928, 1929, and 1930.

According to the figures for 1930, New Hampshire had the lowest recorded murder rate, as shown in the Whitfield data, among the 42 reporting states. Only 4 homicides were registered and the rate per 100,000 population was 0.8. The 5 New England states of Maine, New Hampshire, Vermont, Massachusetts, and Rhode Island, with an aver-

age of 132 people per square mile and numerous large cities, had an aggregate average rate of only 1.4 which is by all odds the lowest recorded for the various geographical groups of states.

The highest average for a geographical group of states was 20.9 homicides per 100,000 population, the rate for the East South Central states of Kentucky, Tennessee, Alabama, and Mississippi, where there are only 55 inhabitants per square mile.

The densely populated Middle Atlantic states of New York, New Jersey, and Pennsylvania, with 263 people per square mile, had an average rate of 5.2 compared with 7.3 in the East North Central group with an average of 103 people per square mile and among which Illinois led with 10.5 murders per 100,000 people.

The three Pacific states, with only 26 inhabitants per square mile, had an average rate of 5.2, a figure identical with that for the three Middle Atlantic states and somewhat higher than the figure for the West North Central group, where the density is 26 people per square mile and which had a murder rate of 3.6 per 100,000 population.

While in general the states with a large Negro element in the population experience excessively high homicide rates this does not appear to be the only important determining factor. The New England and the Pacific states, for example, have each almost exactly 1 per cent Negro population and yet the homicide rate in the former was 1.4 against 5.2 in the latter.

Again the homicide rate in North Carolina and in Illinois was almost identical, 10.9 and 10.5, respectively, although Negroes make up 29 per cent of the population in North Carolina and only 4.3 per cent in Illinois. Also in South Carolina the Negro population is 46 per cent of the total against 8.6 per cent in Kentucky, but the murder rate in South Carolina was only 13.9 per

100,000 population, whereas in Kentucky it was 18.6. Mississippi, on the other hand, where 50 per cent of the population is Negro, had a murder rate of 25.7, the highest in the country, but Tennessee had a homicide rate of 18.9, although Negroes make up only 18 per cent of the population. Again, New Jersey has 5.2 per cent Negroes in the population against 4.3 per cent in Illinois, but the murder rate in New Jersey was 5.0 and that in Illinois 10.5. Furthermore, the density of population in New Jersey is 420 per square mile and that in Illinois 116.

This is clear evidence that factors other than race, color, and density of population are involved in the homicide rate. While these statistics relate to the 1930 experience only, there was no great difference in the relative rates in the various states during the 3 years 1928-1930.—*Illinois Health Messenger*, 4: 15-16 (Feb. 15), 1932.

**The Population of the Netherlands**—The population of the Netherlands has increased rapidly during the past 100 years. From 1829 to 1928 it rose from 2,613,487 to 7,730,577, an increase of 195.86 per cent. This increase in population has been especially rapid during recent years as is illustrated by the fact that during the 70-year period from 1829 to 1898 it increased 100 per cent, while from 1899 to 1928 it increased 66 per cent. Since 1920 the increase has been at the rate of approximately 100,000 per year. This increase resulted in 1928 in a population density of 585.1 per square mile, placing the Netherlands second to Belgium among the European nations in this respect.

As emigration has exceeded immigration, the recent increase in population must have been due to an increasing birth rate or a decreasing death rate, or both. The birth rate in the Netherlands rose until approximately 1875, and has declined steadily since that time.

The fairly rapid decline within recent years is doubtless due in part to the great emphasis placed on birth control. On the other hand, the death rate per 1,000 has declined for the past 100 years, but the decline has been especially rapid since 1875.

The figures indicate that the increase in population was chiefly due to an increasing birth rate until the last quarter of the past century, while since that time the declining death rate has played the most important part.

The changes in birth and death rates have not been uniform in all sections of the country. Both have decreased least in the southern provinces. These are the sandy soil areas which developed later than the central clay districts. In North-Brabant, for example, the birth rate per 1,000 was 28.98 in 1927; this was considerably above the figure for the country as a whole, which was 23.11 in the same year, and was exactly the same as the average for the same area for the period 1840-1849. It is only fair to say, however, that between these two periods the birth rate in the province had risen to 34.13. In this same area the death rate did not start to decline until 1870, although throughout most of the rest of the country it had been declining for at least 40 years prior to that date. It has been in the older provinces, for the most part, that the decline in both birth and death rates has been greatest. This has been especially true in North and South Holland. The exact reasons for this are difficult to determine.

Historical, social, and economic factors have all played their parts. These centers were the first to develop economically and have experienced the greatest prosperity. They have also been the centers of the intellectual life of the country and here medical science and sanitation reached their highest development. On the sandy areas the economic and intellectual awakening was

later in arriving. These factors, at least in part, account for variations in the birth and death rates in the two sections.

The birth and death rates and the increase of population vary in communities of different sizes. The larger communities have been increasing in relative importance while the smaller ones have been losing ground. In spite of this, the larger cities have a lower natural increase than the smaller towns. In 1927 communities of more than 100,000 had a death rate of 9.17 per 1,000, while communities of less than 5,000 had a rate of 11.35. In the same year communities of over 100,000 had a birth rate of 18.88, while communities of less than 5,000 had a rate of 25.69. As the variation in birth rates is greater than that in death rates, the increase in population from natural sources is more rapid in the smaller communities. The increasing importance of the larger cities must thus be accounted for by the fact that they are attracting large numbers of people from the smaller towns.—J. F. Bogardus, *Economic Geography*, 8: 43–45 (Jan.). 1932.

**Marriages of Girls 14 and 15 Years of Age**—An analysis of the marriage records of the State of New York outside of New York City for 1930 shows that in 230 marriages the bride was under 16 years; 33 brides were 14, and 197 brides 15 years of age. The distribution of the ages of the grooms

whom these girls married, was as follows: under 20 years, 46; 20–24, 132; 25–29, 32; 30–34, 13; 35 years and over, 7. The youngest groom was 16, the oldest 51 years of age. The median age of the grooms of the 14 year old brides was 22.8 years; of the 15 year old brides, 21.3; and for the combined ages, 21.5 years.

The assertion is often made that child marriages are largely confined to that section of the population which is of foreign birth or of immediate foreign origin. The figures, however, do not support this statement. Of the 230 brides, 10 were foreign born; 5 natives of Italy and 5 of Canada. Of the 220 native born brides, 153 were of native parentage, 12 of mixed parentage, and 55 of foreign parentage. Relating these numbers to all marriages in the several nativity groups, it is found that these child marriages represented 6 in 1,000 of the native born brides of native parentage, the same proportion in the group of native born brides of foreign parentage, while among native born brides of mixed parentage only 2 in 1,000 were 14 or 15 years old.

Among the grooms, 47 were foreign born: 23 were natives of Italy; and 6, of Canada; the remaining ones were natives of twelve different countries. The native born grooms were divided according to parentage as follows: native, 129; mixed, 23; foreign, 31.—*Health News*, New York State Dept. of Health, 8: 230 (Dec. 21), 1931.

# PUBLIC HEALTH ENGINEERING

## THE SANITARY OFFICER IN RURAL SANITATION\*

H. W. VAN HOVENBERG

*Sanitary Engineer, St. Louis Southwestern Railway Lines, Texarkana, Tex.*

PERSONAL contact with and observations of the working of county health units and of rural sanitation projects in those counties in states served by the St. Louis Southwestern Railway and other railroads with which I have been associated, suggest these personal views on the present plan of operation of county health units. Nothing I may say should be construed as a criticism of the present plan, or of those with whom it has been my pleasure to be associated, but rather as thoughts for discussion, based on the desire of some of the personnel engaged in rural public health work to make it more effective.

Much has been written of the multiple necessities for county health units, of progress being made, and of what the future holds for their personnel. If we discount the enthusiasm of many of these writers we still have a considerable sum total of accomplishment. This same enthusiasm may have occasionally overreached itself in assigning dollar and cents values to achievements, particularly from the sanitary engineering viewpoint. I refer to the comparative values of privy installations versus sewerage systems and safe water supplies, and to widespread typhoid vaccination with no attention being paid to providing safe water and milk, or to proper screening. Immunization has its

proper place, but surely not to the exclusion of basic sanitary health protective measures.

I think it is entirely proper and feasible to include the sanitary portion of rural health work in our southern states within the province of those basically trained in sanitary engineering or those having had instruction fitting them for inspection and disposition of sanitary problems. I refer particularly to rural water supplies, fly and mosquito control, screening, milk production, insect and rodent eradication about the house, and human waste disposal. These, with some others, might be grouped under the heading of environmental sanitation problems. We readily realize that such activities are basic since proper control measures are aimed wholly toward prevention of disease, and, while directed toward the home in most instances, their province and indirect influence extend over the hamlet and city as well. Hookworm, malaria, and dengue, and diseases carried by infected water and milk, can be controlled by proper application of environmental sanitary measures. In my opinion too many of our present health units are missing a wonderful opportunity in not making greater provision for such work.

In seeking the reason for this delinquency, as I may choose to call it, it appears that in our present conception of unit health work, the strictly sanitary functions are being underemphasized. This may be due to a number of reasons, possibly to lack of appreciation of

\* Read before the Public Health Engineering Section of the American Public Health Association at the Sixtieth Annual Meeting at Montreal, Canada, September 17, 1931.

such phases of public health work; possibly to inability to secure trained sanitary personnel, but more likely to the confusion in the minds of many otherwise capable men who choose not to view public health work from the broad viewpoint of joint coöperation and responsibility of the medical officer, the sanitary engineer, the bacteriologist, the serologist, the veterinarian, etc.

My feeling is that the so-called standard county health unit can be decidedly improved with a relatively small additional cost. I would suggest no change in the present personnel of doctor, sanitary inspector, nurse, and clerk, but rather for better trained sanitary inspectors, better paid sanitary inspectors, and for trained sanitary engineering supervision for such inspectors, rather than medical officer direction of these sanitary inspectors. Such a plan reserves to the medical officers at the head of our units all the authority granted them by law, all the prerogative of planning health work and of policies to be pursued, but relieves them of immediate direction of sanitary work, and passes this responsibility on to district sanitary officers or engineers, who in turn report to the state sanitary engineer. In other words, just as provision is made for supervision of unit medical directors, so should qualified direction be provided for unit sanitary inspectors, and this can be done without changing the routine working of the units.

But first of all, I would dignify the position now held by the sanitary inspector by changing his title to sanitary officer, and he will be so designated in the balance of this paper. Such a plan will not be an entirely new departure, but I think its merits are obvious. It provides for complete coördination of public health medical and sanitary policies through the present medical director of county health units and the state sanitary engineer, or engineering bureau director, which is of vital impor-

tance and is the logical first step in any state-wide health program.

After a definite plan of county health unit activity is decided on, then the sanitary engineering functions, delegated to the state sanitary engineer, will be put into effect by district sanitary engineers, or sanitary officers, who have direct supervision over the county health unit sanitary officers. These district men, with offices in their respective districts, and in charge of sanitary engineering activities in say ten counties, would be the contact men between the unit sanitary officers and the unit medical directors. Local health unit policies would then be handled with promptness. The advice of the district sanitary engineer, a man of professional and practical experience, would be available to the medical director, in the handling of problems with which he is not familiar.

The unit sanitary officer, under district supervision, could share offices, equipment, and stenographic help with the medical director, if advisable, but this would not be necessary. It surely would be advisable to have the medical officer wholly acquainted at all times with the work of the sanitary officer, but difference in personal opinion on the prosecution of coöperative unit health work should be handled by their immediate superiors. A close, harmonious, and self respecting understanding between the medical and sanitary officer could thus be maintained—each an expert in his own profession, and making no pretense toward running the other's business.

There will be reasons for objections to such a proposal. We may be told that a similar plan failed after due trial. Perhaps the failure may have been due to lack of trained sanitary supervision, or to other local handicaps. Surely we can find comparable disappointments in whole time unit activities. In a plea for sanitary engineering supervision of unit sanitary officers, we can speak in

generalities of some of the reasons why this is preferable. Few of our medical directors are qualified by training or have the time to take from the multiplicity of their other non-sanitary activities to direct sanitary engineering work properly. Some of them surely lack the personal inclination for it. Under such conditions, any latent executive ability, when present, cannot very well assert itself, and the inspector becomes an orphan waiting for inspiration that never comes, and is too timid under the penalty of loss of position to be self assertive. In fairness to some of the inspectors who have given up public health work, I think it may be said that they tried and failed, but the fault was not their own.

If there is a basic error in our conception of the present health unit organization, it is that an educated man, skilled in his work, able to contact the lowly and the mighty, and fired with enthusiasm, is not at least a junior partner, with some provision made to reward ability by promotion. Such a condition does not exist at present. Yet we have in our counties the county agricultural agent, a comparable position in my mind with what the sanitary officer should be, and for whom no one need offer apologies. Perhaps the day will come when the county sanitary officer will enjoy the same prestige, the commensurate salary, and the opportunity for increasing health and happiness that the county agent enjoys in his chosen sphere.

Men trained to fill the positions of sanitary officers, as distinct from sanitary inspectors, will be hard to find. I know of no school of instruction for them such as has been available to others engaged in unit work, or as has been available to the layman who with

a few weeks' instruction becomes a full fledged sanitary inspector. Our schools are graduating men in courses in sanitary engineering or allied subjects who can fill the sanitary officer positions, and who can get their first taste of the practical application of their profession under expert leadership with the plan just presented.

The cost of the present standard county health unit would be increased under such a plan, principally by the increased salary of the sanitary officer. I suggest the average salary increase, over what now prevails for the sanitary inspector, should approximate \$900 a year, or less than 10 per cent of the present unit cost. Part of this increase might be taken from the present budget items without material damage. We now have some states with district sanitary engineering directors. In those states not so progressive, the expense of district sanitary engineers or officers would have to be provided. In the territory with which I am more familiar, one district sanitary engineer could readily supervise the work in ten counties, making the average cost per county, if placed on this basis, not over an additional \$540 a year, assuming a \$3,000 salary, \$900 traveling expenses, \$900 stenographic assistance, and a \$600 contingent fund, for the district man.

With or without the district engineering supervision of the county sanitary officers, but presupposing efficient state sanitary engineering direction, such a plan as outlined will be a decided improvement, with perhaps the greatest good coming from the coördination in state- and county-wide planning of rural health work of medical and sanitary engineering science, something in my opinion greatly to be desired.

# FOOD AND NUTRITION

**Proteins of Breads Baked from Rye and Wheat Flours Alone or Combined with Yeast or Soya Bean Flour**—These experiments were conducted in Poland and the biological analysis of 17 products is discussed in the present paper. These are divided into 3 groups: (1) various breads commonly consumed in Poland, (2) experimental breads, (3) soya bean flour and baker's yeast. In the preparation of the breads special interest was shown in combinations of rye and wheat flours with varying amounts of baker's yeast and of soya bean flour. The numerical method proposed by Osborne, Mendel and Ferry (*J. Biol. Chem.*, 37: 223) was used for the estimation of the biological value of the proteins of the products studied.

The experiments were made on rats and were usually of 30 days' duration. The composition of each bread used is given, as well as a table showing the protein intake, total intake, gain in weight, etc., on each kind of bread fed.

While the authors made no definite conclusions, the figures would indicate that rye breads in general are superior—so far as the biological value of the protein goes—to wheat products, and that darker rye breads made from less refined flour are superior to lighter varieties. It is also indicated that whole meal rye bread baked from 100 per cent rye flour is inferior to dark rye bread prepared from 82 per cent flour. This might be due to the presence in whole meal rye bread of large amounts of indigestible roughage derived from the grain husks and interfering with the normal utilization of the proteins.

A supplementary relation was found to exist between the proteins of white

wheat flour and those of baker's yeast, and also between the proteins of white wheat flour and soya bean flour. There is a strong indication that a supplementary relation exists between the proteins of rye flour and of soya bean flour. The biological value of the nitrogen of crust was found to be lower than that of crumb or of whole bread.—S. K. Kon and Z. Markuze, *Biochem. J.*, 25: 1476, 1931.

**Experiments on Nutrition, Comparative Vitamin B<sub>1</sub> Values of Food-Stuffs. Fruits and Vegetables**—Tests on the vitamin B<sub>1</sub> values of 30 common fruits and vegetables were made on pairs of pigeons. The preventive method of testing for the presence of vitamin B<sub>1</sub> was used throughout the series of experiments. Cooked vegetables and fruits were used as the means of procuring consumption. No objection can be made to this procedure since many workers have shown that vitamin B<sub>1</sub> is not destroyed by a temperature of 100°. In the first trials with fruits and vegetables 50 per cent of the fresh food was mixed with the flour and fishmeal. Most of the pigeons showed head retraction in from 3 to 9 weeks. After 9 weeks 70 per cent or 80 per cent was then tested.

In no case were the pigeons maintained when the fruit composed 50 per cent of the diet. With 70 per cent of the diet composed of fruit, maintenance was not longer than 9 to 11 weeks, except in the case of orange juice and orange peel. With 80 per cent of tomatoes the birds were maintained for the test period of 26 weeks or more. The test indicated that orange peel is equal to orange juice in vitamin B<sub>1</sub>, but

the general appearance of the birds leads to doubt. It is suggested that the oil in the rind has some medicinal action.

Pigeons were maintained on a diet with 80 per cent of cabbage, and 80 per cent of watercress. Lettuce and spinach at 80 per cent and 70 per cent failed to secure maintenance for 26 weeks. Brussels sprouts showed very little vitamin B<sub>1</sub>.

Of the roots and tubers tested, artichokes, leeks, parsnips and potatoes contain some vitamin B<sub>1</sub>. Beetroot, carrots, swedes, and turnips contain very little.

The results here do not indicate that vegetables and fruits have any important value as a source of vitamin B<sub>1</sub> in the general human dietary. In order to supply sufficient vitamin B<sub>1</sub>, from 60 per cent to 80 per cent of the diet must be composed of these foodstuffs in the fresh state, amounts impossible for man to consume. The amount of vegetable usually eaten by man is not alone enough for his vitamin B<sub>1</sub> requirement.—Robert Henry Aders Plimmer, William Henry Raymond, and John Lowndes, *Biochem. J.*, 25: 1788, 1931.

**The Antiscorbutic Vitamin in Home-Canned Carrots**—The purpose of this study was to determine the difference, if any, of the effect of pressure-cooker and water-bath processing on vitamin C potency. Carrots were used because they are a good source of vitamin C and because both methods are employed. When the water bath is used it is customary to add a small amount of vinegar or lemon juice to increase the effectiveness of the heating process in killing microorganisms. The carrots were canned in 3 ways: (1) water bath with vinegar, (2) pressure cooker with vinegar, and (3) pressure cooker without vinegar.

Normal guinea pigs, weighing about 350 mg. were fed a basal diet, lacking in

vitamin C, consisting of ground oats, wheat bran, skim-milk powder, butterfat and sodium chloride. To insure vitamin D sufficiency, in some of the later experiments, cod liver oil replaced 2 per cent of the butterfat.

The results indicate that practically all the vitamin C present in raw carrots is destroyed when carrots are cold packed with a small amount of vinegar and heated in a water bath for 90 minutes, or are processed with or without vinegar in a steam-pressure cooker for 40 minutes at 10 lb. pressure. A daily dose of 15 to 20 gm. of raw carrots was required to protect a guinea pig from scurvy, but even when 50 gm. of canned carrots were fed, most of the animals developed severe cases of scurvy and all of them died before the end of the test period. No difference was noted in the carrots processed in the pressure cooker with and without the addition of acid.—Adelaide Spohn and Amy Hunter, *J. Agri. Res.*, 43: 1101 (Dec. 15), 1931.

**The Antiscorbutic Vitamin in the Juice of Home-Canned Tomatoes**—Since carrots are representative of the "nonacid" class of foods, and since they were shown to lose their vitamin C potency when home canned, it was considered of interest to determine the effect of home canning on a food having a natural pH greater than that of carrots. Tomatoes were chosen since they are a typical acid food. Two varieties of tomatoes, Globe and Bonny Best, were used. They were cold packed and processed for 20 minutes. Guinea pigs, weighing an average of 350 gm. were fed a basal diet of skim-milk powder, ground whole oats, wheat bran, butterfat, and sodium chloride. The control group received only the basal diet and distilled water, while the remaining animals received in addition 1 to 4 c.c. of either canned or raw tomato juice.

A considerable loss of vitamin C in the canned product. was indicated. Three and one-half c.c. of the raw tomato juice was sufficient to protect the guinea pigs from scurvy, while 4 c.c. of the juice of the canned tomatoes failed to protect the animals.—Adelaide Spohn, *J. Agri. Res.*, 43: 1109 (Dec. 15), 1931.

**Vitamin G and the Growth Factor in Tomato Juice**—The animals used in this experiment were young rats, approximately 4 weeks old, weighing 30 to 40 gm. each. They were placed in individual screen-bottomed cages and fed the following ration: casein, corn-starch, Osborne and Mendel salt mixture, lard, and 2 drops of cod liver oil per rat daily. After 1 week of depletion on the basal ration devoid of all factors of the B complex, constant weights were obtained. Graded doses of tomato juice were then fed daily in separate cups for an 8 weeks' period. Weights of the animals were recorded daily as well as symptoms of deficiency.

In the groups that lived long enough to develop a dermatitis, it always appeared in approximately 44 days, regardless of the amount of tomato juice fed. That the dermatitis was of nutritional origin, and not of epidemic nature, is indicated by the fact that the rats were kept on the same racks as some rats used in vitamin A assay experiments, and these showed no dermatitis. This shows the absence of vitamin G from the tomato juice.

On the smaller quantities of juice, the rats showed a loss of weight and on the larger doses a gain. It is shown that this gain cannot be correlated with any presence of vitamin G and probably is not related to the presence of vitamin B ( $B_1$ ) since previous experiments (*Biochem. J.*, 24: 1827, 1930, *J. Biol. Chem.*, 89: 275, 1930) have shown the absence of growth when rats were fed an abundance of this vitamin. This growth factor, therefore, probably

is Reader's  $B_4$  or the vitamin F, of which Sure, Smith and Kik speak (*Science*, 73: 242, 1931).—R. G. Daggs and A. G. Eaton, Dept. of Vital Economics, University of Rochester, Abstract, *Science*, 75: 222 (Feb. 19), 1932.

**An Economical Method of Producing Acidophilus Milk**—The method reported by the author is claimed to overcome some of the difficulties encountered in the commercial production of acidophilus milk. It is stated that the problem involved in the manufacture of acidophilus milk is possibly that of eliminating fast growing sporulating organisms.

The method consists in incubating skim milk at 37° to 47° C. for 2½ to 3 hours, heating to as near the boiling point as possible for 30 minutes, quick cooling at 37° to 40° C., prompt inoculation with an active culture of *Lactobacillus acidophilus* and holding at that temperature until coagulation takes place.

The method is certain to give a better product than the one now in use, and has the merit of cutting in half the time required to prepare the skim milk for inoculation.—Georges Knaysi, *J. Dairy Sci.*, 15: 71 (Jan.), 1932.

**The Effect of Pasteurization upon Brucella Melitensis Var. Suis**—A series of experiments are reported upon the pasteurization effects of bovine and the more heat resistant porcine strains of Brucella. The authors concluded that pasteurization tests, using a standard pasteurizing outfit show that a temperature of 62°–63° C. (143.6°–145.4° F.) applied 3 minutes is sufficient to destroy Brucella organisms, both the bovine and porcine varieties.

This indicates that the usual pasteurization temperature of 62–63° C. for 30 minutes gives an ample factor of safety providing the pasteurizer is operated properly.

With the lid of the pasteurizer open, a much longer time exposure to this temperature is required, and the results obtained are irregular and uncertain in that viable organisms were recovered from the foam even after 30 minutes pasteurization. The absolute necessity of a flush gate valve is also indicated, for in those experiments in which an ordinary faucet outlet was used, viable organisms were obtained

from the outlet after 30 minutes' pasteurization, whereas, with the outlet closed by a stopper on the inside, no living organisms remained after 3 minutes exposure.

These experiments emphasize the importance of carefully conducted operations in pasteurization if successful results are to be obtained.—Charles Murray, S. H. McNutt, and Paul Purwin, *J. Dairy Sci.*, 15: 6 (Jan.), 1932.

## INDUSTRIAL HYGIENE

**The Baltimore Gas Appliance Ordinance and its Relation to Public Health**—The use of gas is, as is well known, attended with danger due to the poisonous effects of its carbon monoxide. Many cities have passed ordinances controlling the sale of gas burning appliances in an effort to prevent the occurrences of cases of poisoning. The author briefly reviews the ordinances of Newark, Los Angeles, New York, Hartford, Berkeley, Pasadena, and Baltimore.

The effects of carbon monoxide in producing both acute and chronic poisoning are presented in some detail which need not be abstracted here.

The steps taken in the development of the Baltimore gas appliance ordinance are described at length. This development should serve as a guide to other cities contemplating the promulgation of ordinances regulating gas appliances.

Finally the results of a study of circulating tank water heaters is described. Eighty-nine heaters were tested. Of these, 64 (71.9 per cent) produced less than the specified allowable upper limit of carbon monoxide, namely, 2 parts per 10,000 of air. Three heaters produced between 26 and 50 parts of CO, two produced from 51 to 100 parts and 2

produced between 100 and 200 parts. In no instance did a registered appliance produce dangerous concentrations of CO. One hot water heater in a kitchen was found to be producing a concentration of 170 parts. When the kitchen was closed tightly and the heater was allowed to burn for 1 hour, the air in the room was found to contain 25 parts of CO per 10,000. These very interesting and valuable studies are to be continued.—Wilmer H. Schulze, *J. Indust. Hyg.*, Feb., 1932, p. 41.

L. G.

**Occupational Diseases in the Wood Industry**—The most frequent symptoms of poisoning from wood are the various forms of skin disease. These affections may vary from a slight reddish irritation to a general eczema. Lesions generally make their appearance on the exposed parts of the body first and then later may spread to other portions. Palpitation, shortness of breath and dizziness may become manifest and in more serious cases there may be systemic effects, such as digestive disturbances, glycosuria, and renal disease.

Oftentimes persons who have once suffered from eczema may develop hypersensitiveness so that the exposure to

dust in a room where these toxic woods are being handled may cause a return of the disease.

There are many varieties of tropical woods which contain toxic principles. For its value as a reference the more important of these may be listed as follows: the wood of the date and coconut palm and the tabago palm all generally known as zebra wood; moule wood of West Africa; ironwood from the West Indies; West Indian greenheart, rosewood or blackwood, satinwood, renghas, amboyna, teak, ebony, boxwood, and others.—*Bull. Internat. Union Woodworkers* (Berlin). Abstr. *M. L. R.*, Feb., 1932, p. 301. L. G.

An Investigation of the Kelley Dust Trap for Use with Pneumatic Rock Drills of the "Jackhammer" Type—The Kelley dust trap consists of a small metal chamber, in form somewhat like an inverted tin water dipper, which is designed to enclose the steel drill rod used in rock drilling, at the point where the drill enters the rock. It does not fit about the drill rod tightly nor does it make an airtight seal at the rock surface. The dust trap is connected to a source of suction by means of a flexible hose.

As a result of these studies, it was found that 60 cu. ft. of air per minute per drill are required in order to maintain the atmosphere in the neighborhood of the worker at 5 million particles per cu. ft. of air, when tested with the Greenburg-Smith impinger apparatus. Certain additional engineering data of value were obtained during the course of this study. These data need not however be presented here.

This is an exceedingly important contribution and one which should have a far reaching bearing on the control of silicosis in rock drilling.—Theodore Hatch, George S. Kelley, and J. William Fehnel, *J. Indust. Hyg.*, Feb., 1932, p. 69. L. G.

Fatigue in Soldier's Due to Chlorine Losses—Pathological fatigue is no longer solely attributed to the accumulation within the body of waste products of muscular effort. Both bodily and environmental conditions directly contribute to it, and an extensive bibliography has been prepared on industrial fatigue by the Committee on Industrial Fatigue and Allied Subjects of the American Public Health Association as well as a valuable Review on Physiological Effects of Abnormal Temperatures and Humidities, by R. R. Sayers and Sarah J. Davenport of the U. S. Public Health Service.

Conditions surrounding military training or actual warfare are often conducive to gross losses of body fluids due to sweating. (A discussion is devoted to the subject of the chemistry and physiology of perspiration, including the amount of water eliminated under certain conditions; likewise, a section on the changes in chloride constituency of sweat, blood, and cellular tissues associated with sweating.)

Among numerous reports indicating the practicability of replacing chloride losses, following profuse sweating, by the addition of sodium chloride, is an instance in which a group of 14 men working in hot mines, where fatigue and cramps prevailed, obtained gratifying results when given 0.25 per cent of sodium chloride to the gallon of drinking water. Likewise, Oswald, Haldane, Marschak and Dukelskaga and others have reported favorably upon the disappearance of symptoms, associated with overheating, through the use of saline solutions. The desire to eat salted meat such as salted red herring among British miners engaged in hot work is undoubtedly a point in illustration. Scores of industries are now supplying salinized drinking water for the purpose of replacing unwanted losses of minerals in sweating. It is felt that the use of tablets of salts for this purpose

are potentially dangerous since they may cause stomach irritation.

As sweating is prolonged the percentage of chlorides increases in the sweat, and in an average case the loss from the body of chlorides approximates 20 gm. per day—much more than would normally be replaced in the chlorides of foods and drinks. Obviously, water alone does not alleviate the condition.

A 0.5 per cent solution of sodium chloride in the face of excessive sweating should promote a sense of comfort and well being, avoid cramps in muscle groups and in the intestinal tract, avoid the deprivation of minerals and water in the tissues, and prevent gastric hyp acidity. The use of 0.5 to 1.0 per cent of common salt in drinking water is recommended for military purposes under all conditions conducive to undue chloride losses in personnel. (Bibliography follows.)—Carey P. McCord, *Military Surgeon*, 69, 6: 608–614 (Dec.), 1931. E. R. H.

**Hydrocyanic Acid Gas Poisoning by Absorption Through the Skin—**This brief contribution presents a review of the literature of hydrocyanic acid gas poisoning by skin absorption.

Three cases of poisoning by skin absorption are briefly described. In all these cases satisfactory respiratory protection was had, yet poisoning occurred when the men were in an atmosphere of 2 per cent of hydrocyanic acid gas. The symptoms developing in 8 to 10 minutes of exposure were dizziness, weakness and throbbing pulse. Several hours after exposure marked weakness, high pulse rate and headache still persisted.—Philip Drinker, *J. Indust. Hyg.*, Feb., 1932, p. 1. L. G.

**A Pressure Chamber Installation for Studying the Physiologic Effects of Pressures Varying from 6 to 60 lb. per sq. in.—**This is a description of an experimental chamber installed at the Harvard School of Public Health for the study of the physiological effects of pressures from 6 to 60 lb. on the human organism.

A description of the apparatus need not be presented here. The apparatus appears to be excellently designed for the purpose at hand and should yield results of value at the hands of the Harvard investigators.—R. M. Thompson, C. P. Yaglou, and A. B. Van Woert, *J. Indust. Hyg.*, Feb., 1932, p. 57. L. G.

# CHILD HYGIENE

## CHILD HYGIENE WORK OF A COUNTY DEPARTMENT OF HEALTH

ON February 1, 1925, the Fourth Demonstration of the Commonwealth Fund Program for Child Health was officially launched in Marion County, Ore. According to the 1920 census, Marion County had a population of 47,177, only a little more than half of which lived in cities, towns and villages. The rest lived in the open country. Local authorities and committees coöperated with the Commonwealth Fund for a period of 5 years, after which time the work was taken over entirely by local authorities and given the name of the "Marion County Department of Health."

A recent report from Marion County states:

Like many other public health activities, child health is not one which can be carried on successfully when only the child itself is concerned. The whole community must undergo considerable improvement before the children will show improved conditions of health.

Marion County has a population of slightly more than 56,000 (exclusive of several state hospitals and institutions), four-sevenths of which is classed as rural; 85 per cent of the people in the county are native whites.

### *I. Prenatal and Maternal Hygiene*

The very beginning of the child health program of any organization starts with the prenatal and maternal hygiene activities. The nurses in the Marion County Health Department, under the direction of physicians, make visits to prospective mothers, giving instructions in general hygiene and diet and advising regular examinations by their physicians. The value of pelvic measurements, urinalyses, blood tests and blood counts, and blood pressure determinations, are explained . . . All deliveries are made by private phy-

sicians, a large percentage of which take place in the hospitals throughout the county.

### *II. Infant Hygiene*

Nurses also call in the homes of the newborn when requested, for the purpose of carrying on some bedside care and general advice to mothers. In this manner many infant lives are saved, for it is during the first day or the first month that most infants die, and if these difficult days are passed without mishap there is a good chance for the infant to develop into healthful childhood.

Copies of birth certificates or birth notification blanks are made out, and so far as possible they are delivered to the home so that the nurse has an opportunity of coming into direct contact with many of the mothers. This also makes it possible for the nurse to urge the mother to have the baby examined regularly by a physician, who can also weigh the infant and give such advice as is necessary for the proper feeding and care of the baby. At this time the mother is given information concerning the advisability of having her infant immunized against diphtheria and small-pox before it reaches its first birthday.

Clinics are conducted regularly throughout the county in 10 different centers, and at more irregular intervals at other places. To these centers the mothers may bring their babies for weighing and examination by a physician. The clinic does not aim to take the infant away from the private physician but serves rather to point out the value of such examinations, and provides an opportunity for urging the mothers to have their children regularly examined by their own physicians if possible. Defects are pointed out and general advice as to care and diet is given. Except in the case of indigent families, mothers are not urged to bring their infants back to the clinic oftener than 3 or 4 times a year, this number of visits being thought sufficient to impress upon the mothers the advisability of regular examinations. Nurses make follow-up calls to see that the instructions received in the clinic are carried out. The nurses in Salem also conduct demonstrations, at which

time the infants are weighed and the mothers are given general information on child care.

From 1925 to 1931 the infant mortality rate for Marion County has drifted downward from 50.1 to 46.5 in 1931; the year 1930 shows the most favorable rate (36.4) of the period. The city of Salem, which lies in Marion County, shows an even more encouraging decrease in rates from 48.7 in 1927 to 33.6 in 1931. This would indicate that more concentration of work in rural districts is needed.

### III. Preschool Hygiene

The activities for preschool children are mainly a continuation of the infant hygiene work. Clinics to which the preschool child is brought are held in conjunction with the infant clinics. The same type of examination is carried out, and the same follow-up system is used. Health habits are given considerable attention in the clinics, and behavior problems are dealt with in so far as the examining physicians are able to advise. The mothers are advised to consult the family physician and the family dentist regularly. Immunization against diphtheria and smallpox is stressed and regular days are given over to immunization clinics throughout the county. About 50 per cent of the preschool children in Salem are now immunized, and for the county as a whole the percentage is probably a little lower.

While no "round-ups" as such are conducted by the health department staff or any other organization in the county in a wholesale fashion, special efforts are made during the summer months to examine and reexamine as many children as possible before they enter school for the first time in the fall. This is done through the regularly scheduled clinics and appears to be much more effective and satisfactory than using wholesale methods. From one-third to one-half of the new entries in school are thus examined before they enter school.

The blank used for recording the results of the physical examination, called the "health record," is one that is used from infancy through the entire school period, but obviously this is possible only because the same organization is responsible for all the health activities of children in the community.

### IV. School Hygiene

In a school population of a little over 12,000 children, about one-third are examined

each year . . . The health department does not endeavor to do any corrective work except for a few dental defects occurring in children from indigent families. The teachers and nurses cooperate in getting the parents to go to the family physician or dentist, or arrangements are made to send the children to hospitals, dispensaries, and the like, for needed corrections.

The teachers are responsible for weighing and measuring the children in their charge at regular intervals. They test the vision and hearing of each child. Daily inspections are made for the presence of contagious diseases, and the nurses make periodic visits to each school to carry on the usual routine matters. Home calls are made, when necessary, by nurses.

Dental examinations are made on all children in school so far as possible each year, by a dentist on the health department staff. He also does a few corrections, but the great majority are made by private dentists. In 1930, 8,630 children were examined by the school dentist, among which number 6,132 were found to have dental defects. Two hundred and seventy-six of them were treated at the health department dental clinic, and 3,054 received corrections at the hands of their own private dentists. Since the school dentist is only working on a part-time basis many defects went uncorrected.

Immunizations against diphtheria and smallpox are urged, although they are not compulsory for school attendance anywhere in the county except in the event of epidemics. Immunization clinics are held each Saturday morning throughout the year at the headquarters of the health department in Salem. In addition to this, immunizations are also carried out in the schools at least once a year. In Salem it has been estimated, by taking a census in various schools, that 67 to 72 per cent of the elementary school children have been immunized against these two diseases, but the percentage in the remainder of the county is probably slightly lower. Because of the low incidence of typhoid fever in the county, no immunization for this disease is offered, careful attention being given to general sanitation for its prevention . . .

In the schools of the county the May Day programs are a prominent feature. On this day special attention is focused on those who have attained a place on the Honor Roll of the schools. To reach such a place the pupils must have shown:

1. Satisfactory practice of health habits
2. Satisfactory behavior and attitude in school

3. Satisfactory nutrition or gain in weight
4. Freedom from remedial physical defects
5. Evidences of immunity to diphtheria and smallpox

In order to impress the teachers with the value of periodic health examinations, they are required to have a complete physical examination at least every two years. This also tends to eliminate those teachers who are not physically fit and those whose health might be a menace to that of the pupils.

V. Communicable Disease Control

The control of communicable diseases constitutes one of the very important functions of the health department and for the most part is concerned with children. Besides checking communicable diseases by isolation and quarantining cases, following up contacts, and making calls on suspects for diagnosis, control measures are carried on, such as immunization, and also improvement in the sanitary conditions.

The following table of communicable disease incidence will show some of the results of this campaign in Marion County.

VI. Tuberculosis Control

Tuberculosis remains a constant menace to the health of the children of Marion County although a very small percentage of them are to be found with active lesions. The majority of those who die of tuberculosis in the county, or those who show clinical signs of the disease, are among adults, but it must be constantly borne in mind that these adults receive their initial infection in childhood. Control work consists in examining and tuberculin testing all contacts, as well as many who have the disease in the active or arrested stage. Clinics for this purpose are held in various parts of the county and nurses carry on follow-up work on all known tuberculosis cases and contacts.

The tuberculosis death rate for the United States in 1930 was between 85 and 90 per 100,000; for Oregon the rate for the same year was 49.6, while the rate for Marion County was 37.4. At the present time the greatest problem in the control of the disease in the county is in the rural sections, almost three times more deaths occurring in the rural sections than in the urban.

	Smallpox		Diphtheria		Typhoid		Scarlet Fever	
	Cases	Deaths	Cases	Deaths	Cases	Deaths	Cases	Deaths
1924	32	1	265	17	9	2	79	1
1925	181	0	165	17	4	1	47	2
1926	53	2	87	2	17	1	71	0
1927	39	0	41	1	28	3	54	1
1928	26	0	23	0	8	0	51	0
1929	36	0	24	1	4	1	56	0
1930	12	0	41	0	4	1	35	0
1931	10	0	20	2	3	0	44	1

PUBLIC HEALTH NURSING\*

The Public Health Nurse and Her Uniform—Public health nurses are constantly making pictures of themselves, and what the world knows of them depends largely upon the kind of picture they present. The line, color and texture of a nurse's clothes play a big part in this picture, and the wise nurse makes them work for her by hav-

ing them express the strength, firmness, robustness of purpose, maturity and dignity for which her profession stands.

Color makes the first impression. It must be practical, attractive and becoming to the majority. Intense colors, like red and yellow, and dull and muddy ones like browns are equally to be avoided. Light or medium blues are good because they are associated with calmness and serenity.

Dark values are better for street uni-

\* Leave out printed matter or other material relating to public health nursing to Eva F. MacDougall, State House Annex, Indianapolis, Ind.

forms. Clear navy blue, oxford grey, forestry green, or the greenish khaki found in some woolen materials are safe choices. Sharp color contrasts like dark blue and white, cream and greenish khaki, etc., put vitality into a costume.

Materials should be heavy enough to contradict any effect of flimsiness or delicacy; they should be sportsmanlike and make up well in a tailored style.

The straight lines are those to be emphasized in a uniform. "A widely pleated straight skirt is better than a more finely pleated one. A gored or a six gored skirt is better than a circular cut. A collar with a plain straight edge is better than a scalloped one. Long sleeves are better than short. . . ." Bows and lace should never be worn. If a pin is worn it should not be a delicate exquisite thing, but one of good size, hardy in character, with no bright and shining jewels.

It is best to have the uniform coat long enough to cover the dress, so there can be a long unbroken line. All the buttons on the coat should function. The coat belt should buckle rather than tie. Large pockets are better than small ones on a coat.

The uniform hat can express the same smart severity and sturdy sportsmanlike character that the good uniform coat expresses. Felt is good material. There is no place for fluffy trimming, perky bows or shining pins, however. If there must be trimming, grosgrain ribbon or a leather band, kept flat, is best.

The shoes should be uniform, too. They should be no more frail than the hat or coat. This eliminates modified oxfords with many cut-outs and shoes with three or more straps. The heels should have a decently large walking surface. It is best to keep the color of the shoes dark. Shoes and handbag should match.

Flowered chiffon scarfs are not to be worn with a uniform coat; they are for

other occasions. A double silk or a soft woolen scarf goes better with the heavy texture of a uniform coat.

Cast-off dress gloves with fancy stitching and wrist bands go as badly with a uniform coat as a flowered chiffon scarf does. Gloves of the simple pull-on type with plain stitching are best.

Dainty lace or embroidered handkerchiefs do not go with the uniform. They should be of good size with a fairly wide hem.

Clothes should fit the times as well as the person and occasion. For instance, the health worker should not wear her belt 5 inches lower than the waist when every other woman has hers at the waist line, nor should she wear her skirt at knee length if medium length skirts are being worn.

To sum up:

The successful uniform of the public health nurse must be a composite expression. It should indicate the high purposes of the profession, recognize the environment where it is worn, suggest current fashion to a degree that reflects the best of the times in which we live, and consider the individual nurse sufficiently to make her feel at home in her professional costume. Its artistry makes the nurse good to look at, and creates a pleasant attention bespeaking confidence. When it accomplishes this, it makes a contribution not many of us know how to perform for ourselves in our own costumes. Such a uniform is a professional asset.—

Bessie Cameron McDermid, *The Uniform—A Professional Asset*, *Pub. Health Nurs.*, XXIV, 2: 95-98 (Feb.), 1932.

Appropos uniforms the *Semi-Monthly News Letter*, West Virginia State Department of Health, Feb. 17, 1932, has this to say under "We All Like Uniforms":

The effect of the neat trim uniform of a public health nurse on the pupils in a rural school was shown recently when one of the boys in the fourth grade asked to be excused from class while the nurse was inspecting the children in the third grade. In a short time he returned with a broad smile, a very clean,

freshly scrubbed face—and his Sunday suit. Thus had the nurse's immaculate appearance brought about a result that the teacher had been working on for weeks.

**Joint Biennial Convention of Three National Nursing Organizations**—Texas will be hostess for the biennial convention of three national nursing associations, the American Nurses' Association, the National Organization for Public Health Nursing, and the National League of Nursing Education, in San Antonio, April 11–15, 1932.

The following program for the joint sessions of the three organizations offers discussions on questions vital not only to nurses but also to the public which stands in need of the commodity which the nurse has to sell, and indicates the realization of a crisis in the profession of nursing and a serious attempt at finding a fair way to meet it:

*Tuesday, April 12*

Subject: Nursing at the Cross-Roads.

A. Implications for nursing in the findings of two 5-year studies.

The Costs of Medical Care Committee.

The Grading Committee.

B. Significant Adjustments in Nursing Service.

C. Partnership with the Public.

*Wednesday, April 13*

Subject: Next Steps for Nursing.

A. How shall we select and prepare the undergraduate nurse?

B. How shall we select and prepare the graduate nurse?

C. How shall we distribute nursing service equitably?

Subject: Mental Hygiene through the Profession.

A. The Growth of Mental Hygiene.

B. A Mental Hygiene Point of View in Nursing.

C. Attempting an Application in the Various Fields of Nursing.

Evening—Subject: The Economic Situation.

Still keeping these larger questions in mind, special groups will meet to dis-

cuss special problems. Private duty nurses will discuss the need for keeping up with new developments and how. The government nurses will give and take ideas about their problems, and the legislative section of the American Nurses' Association will discuss fundamental principles to be incorporated in a nurse practise act.

Board and committee members of public health nursing services will tackle the fundamental problem of how we are to make our services meet the needs with our restricted budgets.

State and official groups of public health nurses will discuss team-play between official and nonofficial agencies and between public health nurses and social workers.

Staff nurses, school nurses, industrial nurses, course directors, state advisory nurses, and teachers will meet in special sessions to discuss questions pertinent to their fields.

This opportunity for the give-and-take of ideas, for the reunion of friends and fellow-workers under the blue sky of Texas, is one which comes at a time when fresh courage which comes from exchanging experiences is greatly needed.

**Education for Public Health Nursing Board Members**—The duties of public health nursing board members are to employ a competent executive, keep themselves informed about the work of their agency, develop the agency's program, and interpret its work to the community.

But, as George E. Vincent says in the introduction to *The Board Members'*

*Manual*, "Board members are not necessarily congenitally and automatically endowed with capacities and aptitudes for their duties. They too require special knowledge and technical efficiency." How can the board tell who is a competent executive or interpret intelligently the professional histories of the applicants (if they know where to get them) if they do not know the standards of qualification in this particular field? If the board members are not in touch with what is being done in the whole public health nursing field, how can they judge the accomplishments of their own agency? If they do not know the general objectives of their own program, how can they interpret them correctly to the community?

For several years now public health nursing board members have been trying to equip themselves to meet intelligently the problems of their public health nursing program. They have been holding institutes in various parts of the country at which they have discussed board organization, standards of volunteer service, publicity, community responsibility, etc., under expert leadership.

A special department for board members was set up in *Public Health Nursing*, the official magazine of the National Organization for Public Health Nursing, which deals with their interests. A special section of the biennial convention in 1928 was organized for board and committee members. State nursing

conventions soon followed this example. Later board members developed so much activity that a full-time lay secretary to represent them was added to the staff of the N. O. P. H. N.

A twofold study program for board members was planned last October by the N. O. P. H. N. One part of the program is for city public health nursing groups, the other for rural or county groups. It is interesting to know that 125 boards are working on one phase or another of this program. Some of them are beginning to get interested in knowing what constitutes an ideal program for the health officer in a community and what constitutes good coöperation between the social and health agencies of a community.

Board members are becoming increasingly impatient of fellow members who are content to be on the board, come to occasional meetings, but who are hazy as to what it is all about. Such members are fading out of the picture, or are taking on new life and striving to live up to one of their community privileges and responsibilities. The public health nursing field claims no monopoly of board members alert to measure up to their responsibilities in the organization partnership, but the N. O. P. H. N. is unique in that it is giving thoughtful guidance to this new striving for board education.—Evelyn K. Davis, Board Education, *Mid-monthly Survey*, Feb., 1932, p. 548.

## EDUCATION AND PUBLICITY\*

**N**OW Is The Time—More than ever now is the time for skillful presentation of the claims of health agencies, public and private, for wholehearted community acceptance and support.

And now is the time for critical reviewing of what we have said and done which actually and effectively explains the significance of the agencies which carry on public health activities. The cutting of budgets in some sections seems to imply that we have not done a good enough job of explaining ourselves. This calls for more than "getting our names into the papers." It means more than telling about our activities. Probably the surface indications of general good health may be a handicap at this time. How important is the organized health movement at all times? Have we done what we could to tell the public?

### DATES TO REMEMBER

*Philadelphia, May 15-21, 1932*—This place and date offers the next national opportunity for those concerned with publicity-interpretation-education.

The Social Work Publicity Council will hold luncheon, afternoon, and dinner sessions.

The Educational Publicity Division will hold 5 morning sessions.

The Health Division will hold 5 morning sessions.

The Education and Publicity Headquarters will display many helps for the job, and a wide range of selected samples of publicity. There will be a special demonstration of amateur movies. The Headquarters will offer consultation with specialists in many phases of public presentation of health and welfare topics. Frank Kiernan, of the Massachusetts Tuberculosis and Massachusetts Social Hygiene Associations, is chairman of the session on house organs.

For information address National Conference of Social Work, 82 N. High St., Columbus, O., or Social Work Publicity Council, 130 East 22d St., New York.

Following are some of the topics to be presented:

Creative Writing In Relation To Social Problems; Dilemmas In Public Relations; Small City Newspapers; National Publicity In Support Of Local Campaigns; Can We Have Better House Organs? and What Shall We Tell The Public Next Year?

*Colorado Springs, June 6-9, 1932*—In the sessions of the National Tuberculosis Assn. will be the following topics:

"Place and Function of Tuberculosis Associations in Relation to Child Health Education," Dr. Kendall Emerson; "Essentials of Health Publicity," Dr. Iago Galdston; "Planning and Conducting Successful Public Health Meetings," W. F. Higby; "Cashing In On E. D. C.," Dr. H. E. Kleinschmidt.

*Denver, June 9-11, 1932*—In the meeting of the Western Branch, A. P.

\* Please address questions, samples of printed matter, criticism of anything which appears herein, etc., to LORETT G. KOUTZABA, 130 E. 22d St., New York, N. Y.

H. A., Dr. Walter H. Brown, Stanford University, will present "Adult Health Education," and Prof. Clair V. Langton and Dr. Thomas A. Storey will present "Teaching Hygiene to Teachers."

There will be Demonstrations of Pre-school and Parent Health Education, Intensive School Health Program, and Health Publicity.

**Ask Your Senator or Representative**—A large proportion of the edition of many government publications is placed at the disposal of senators and representatives. So why not first write to one of them when you want a government publication?

**Expanding Section Membership**—Last month the Council of Public Health Education Section had the privilege of accepting as members or Fellows a considerable and representative group from the list of those who had not been affiliated with any Section.

*We welcome you!* We think we have something worthwhile to offer you in the fellowship of this Section. We are confident that you have much to share with us who have been Section members.

*We invite you* most cordially to participation in Section activities.

**What Is Now Being Told**—Probably more state departments send out weekly press releases than are reported below. We list those releases so that those interested may secure copies. Then the wide variety of topics suggests speculation as to the practicability of anything in the nature of a progressive program of popular health education.

*Connecticut*: "Cause and Cure of Cancer"; "Smallpox Spreads From Bridgeport"; "National Negro Health Week"; "Children Made Fit For School Life"; "Food Values Past and Present"; "Prevalence and Nature of Can-

cer"; "Common Cold Not To Be Taken Lightly"; "Syphilis."

*Illinois*: "Personal Habits and Health In Winter"; "Variation In Adaptability Of Normal People to Environment"; "Non-Fatal Danger of Scarlet Fever"; "Water: Public and Private"; "The Peace Problem Between Mankind And Germs"; "The Moon As a Factor in Human Health And Welfare"; "The Shrinking Family And Its Influence On Health"; "The Challenge Of Colds and Pneumonia"; "When A Cold Is Not A Cold" (all radio talks). Releases, without titles, on following: scarlet fever; widows in population; appendicitis; hydrophobia; bovine tuberculosis; health effects of depression; dental defects by occupational groups; automobile accidents; influenza; polluted air; respiratory diseases; tuberculosis sanatoria; physical examination of milk handlers; the food dollar; diphtheria; birth rate decline. Almost all of above are based on Illinois statistics, probably the fullest use made of state statistical data.

*Iowa*: "I See" (defective vision); "Parents Can Eradicate Diphtheria"; "Disease Conditions In 1931"; "Making the Breaks" (value of prenatal information); "Milk" (when raw milk is safe); "Influenza"; "From Pail To Palate."

*Maryland*: "Don't Wait Until The Teeth Ache"; "Keep The Well Children Away From Those Who Have Colds"; "Child Health Conferences"; "Indispensables" (in diet).

*New York*: "How The State Department of Health Protects Your Milk Supply"; "Depression Lunches" (office workers); "The Sanitation Of Our Surroundings"; "How Polluted Water Is Made Safe For Domestic Use"; "Purification of Public Water Supplies." All report radio talks.

*Oregon*: "How to Buy Food at Low Cost"; "Typhoid In Oregon—1909 to 1931"; "Automobile Accidents Are Preventable."

Other frequent press releases we receive come from the following:

*U. S. Public Health Service*: "Rickets"; "The Prevention and Control of Venereal Diseases"; "The Prevention of the Introduction of Diseases From Abroad"; "Medical Care and Treatment of Merchant Seamen"; "Headache" (radio).

*National Society for the Prevention of Blindness*: "Sight-saving Classes"; "The Eye: Its Relation To Safety."

*Dept. of Health, 139 Center St., New York*: "Fake Food Inspectors"; "A Report Card For Parents" (self-check on attention to child's health habits); "More Good News" (health conditions).

*Detroit Dept. of Health* issues for some weeks have been primarily of local interest.

Almost any of the above releases will be sent upon request to public health workers.

In New York State, at least, much use is made of the mimeographed sheets in answering letters.

**A Board of Diet Strategy**—The array of new low cost diet publications suggests an opportunity for leadership by the department or association.

Here is how one health agency went at it: Samples of the available publications were secured; two or three people made a tentative plan for widespread distribution and various forms of presentation; submitted this plan to representatives of all health and welfare agencies, newspapers, schools and other groups which were interested; and laid plans for a period of months.

Thus waste and over-emphasis were avoided, and competitive, helter skelter distribution was done away with.

Copy of a detailed plan for community low diet education will be supplied free.

American Child Health Assn., 450 7th Ave., New York:

*Emergency Nutrition*, by Henry C. Sherman. 4 pp. 3 cents.

*Food At Low Cost*, by Lucy H. Gillet. 4 pp. 3 cents.

Bureau of Home Economics, U. S. Dept. of Agriculture, Washington:

*Adequate Diets For Families With Limited Incomes*. 16 pp. Free.

*Emergency Food Relief And Child Health*. 10 pp. Free.

*The Family's Food At Low Cost*. 4 pp. Free.

*Getting The Most For Your Food Money*. 4 pp. Free.

Children's Bureau, Washington:

*How To Spend Your Food Money*. 1 p. Free.

Mimeographed news release on the above. Free.

President's Organization On Unemployment Relief, 1734 New York Ave., Washington:

*Food And Nutrition Of Our Children*. 4 pp. Free.

Evaporated Milk Assn., 203 N. Wabash Ave., Chicago:

*Feeding A Family At Low Cost*. 13 pp. Free.

"In Conference" at Piketown Garage—Mark Time and Ben Hustler are leading characters in a group that gets together in the Piketown Garage to settle affairs of state. Ben Hustler is the wise chap. The group appear from time to time in the *Public Health News* of the Dept. of Health of New Jersey. In the issue of Feb. 5, 1932, they talk about pasteurized milk. We have lifted the samples below from the middle of a three page discussion:

Ben tilted back until his chair hit the desk, hooked his heels over the one rung and blew smoke at the light bulb, hanging from the ceiling. "I take more stock in what scientific fellers know and can prove than in opinions handed out at the store. I suppose you heard about the cooked taste and that dirty milk is pasteurized to keep it sweet and how somebody's baby couldn't digest pasteurized milk and . . ."

"Yes sir. That's just what they said," agreed Mr. Time. "What about it? Mostly hooey," asserted Hustler. "It's easy to prove that milk which is pasteurized right tastes the same as raw milk. Get a crowd to taste milk from half a dozen bottles of each kind that have no marks on them and see what happens. They'll not be able to tell the difference."

"Don't they pasteurize milk to keep it sweet?" asked Mark.

"Maybe they used to but that isn't the main idea at present. With cleaner milk and cold refrigerators it isn't necessary. Pasteurization now is a kind of insurance against disease being spread by milk. It kills disease germs and makes any milk safer."—M. S. R.

**Good Work Brings a Title**—Paul H. Stevens has been doing such good work in the preparation of *Health*, New Haven Dept. of Health, that he has been given the title of assistant editor.

*Journal of Social Hygiene*, is "under new management" with Jean B. Pinney, as editor, and Doris G. Chandler, as assistant editor.

Horace H. Hughes has left Community Council of Philadelphia to become administrative assistant (largely health education and publicity) of Tuberculosis and Public Health Committee, State Charities Aid Assn., New York.

#### SCHOOLS—CHILDREN

Every month during the school year the Oregon Tuberculosis Assn., 310 Fitzpatrick Block, Portland, sends *Child Health* to the schools of the state. It is filled with stories and articles for pupils and teachers. Several other state and city associations issue material for the same purpose, but Oregon is different in sending a supplement bearing a calendar for the month and an outline poster design selected from contributions from the schools. Every month a new poster topic is announced. "The picture for the February calendar should be about teeth. . . ."

The usable form of the teaching and meeting material sent out by the Division of Infant and Child Hygiene, Indiana State Board of Health, is easily adaptable by states and cities. A plan, a program or an idea to a single mimeographed sheet makes it easy to sort out what any single teacher, parent-teacher association or other group wishes to use. If perforated at the left would there be any inclination to use a loose-leaf binder? In that case could a simple classification be provided? "May Day," "Plays," and so on?

Health Education in Elementary Schools: A Brief Bibliography for Classroom Teachers Who Are Planning Health Education Activities. American Child Health Assn., 450 7th Ave., New York. 5 pp. Mimeographed. *Free*.

Health Education: A Brief Bibliography for Administrators and Instruc-

tors of Health Education in Junior and Senior High Schools. American Child Health Assn. 4 pp. Mimeographed. *Free*.

References for Health Education in the Secondary Schools. From Health Trends in Secondary Education. American Child Health Assn. 17 pp. Mimeographed. 15 cents.

The above are almost perfect bibliographies. They give enough information to help in making a selection from complete titles. *All are dated*.

#### CAMPAIGNS

April, 1932: Early Diagnosis Campaign sponsored by tuberculosis and public health agencies throughout the United States.

May 1, 1932: May Day—Child Health Day. Consult state committees in every state, or American Child Health Assn., 450 7th Ave., New York.

May 2-7, 1932: National Baby Week in department stores over the country which follow the lead of *Infants'* and *Children's Department* (trade journal), 3 East 35th St., New York.

North Carolina is conducting a "State-Wide-Milk-For-Health Campaign." Details of the essay, poster and rhyme contests are given in *Health Bulletin*, State Board of Health, Raleigh. March, 1932.

Again Illinois will observe Health Promotion Week, announced by the Governor for April 24-30, 1932. The following days are scheduled: "Health Sunday"; "Nutrition Day"; "Dental Health Day"; "Immunization Day"; "Parental Inventory Day"; "Screen and Garden Day"; "Child Health Day." Suggestions for each day's program are contained in *Illinois Health Messenger*, State Dept. of Public Health, Springfield. March 1, 1932.

There is danger of over-elaboration of the George Washington commemoration year so that children may wish that he had never been born. But

health workers may wish to consider what his life offers in health teaching values. A few examples of Washington material have been noted.

"Keep Fit Like Washington" quotes Mrs. Burton Harrison on Washington's athletic ability and vigorous physical life. *Schrylkill Health News*, 207 N. Centre St., Pottsville, Pa. March, 1932.

Washington's early fight against disease is noted in "Washington's Greatest Victory." *Health Pilot*, Terminal Sales Bldg., Seattle, Wash.

A few paragraphs on how George Washington caught smallpox and how he struggled against disease are in "Washington and His Travels." *Junior Crusader*, Wisconsin and Michigan Tuberculosis Assn. Feb., 1932.

The Robert Koch 50th anniversary will be celebrated this year by tuberculosis and other health agencies.

#### HELP WANTED

Notes On Tuberculin Testing, and a printed statement to parents comes from the Buffalo Tuberculosis Assn., 708 Ellicott St. Robert W. Osborn, executive secretary, very much wants something better for interesting parents in tuberculin test. What have you?

#### MAGAZINE ARTICLES

If you tell the editor of a magazine that you like his article on health you encourage the publication of more articles on health topics. If you tell an editor in friendly fashion why an article is undesirable you help to guard against more of the same kind.

Birth Control Symposium, by Ernst, Sanger, Dewey, and others. Includes cartoon by Wortman, and "Asiatic Conflict and Overpopulation." *Nation*, New York. Jan. 27, 1932. 15 cents.

"Is Birth Control the Answer?" by Mary Breckinridge. *Harper's*. July, 1931. Frontier Nursing Service; birth control and peasant people.

"Only a Common Cold" (Jan. 9, 1932); "Cold Weather Is Good For You" (Jan. 30, 1932). *Literary Digest*.

"What Good Are Doctors?" by E. Robert. *Atlantic*. July, 1931. Appreciation; history.

"What Mental Tests Mean?" by Z. C. Franklin. *New York Herald-Tribune Magazine*. Jan. 10, 1932. Not to "grade" but to "guide" teachers and parents.

"Won't You Step Into My Parlor?" by T. S. Winslow. *New Republic*, New York. Jan. 6, 1932. 15 cents. Cosmetic credulities and crimes.

#### HONORABLE MENTION

To Philadelphia Health Council and Tuberculosis Committee: For an effective annual report.

A Time of Increased Needs (Title); 12 pages 6 by 9 inches; ivory dull finish paper; 10 point type in two columns; one line heads running over the two columns.

The financial report indicates \$16,664.58 for Health Education Service—Lectures, moving pictures, radio talks, lantern slides, window displays, exhibits, posters, pamphlets, publications, newspaper and periodical publicity, information and advisory service to aid the sick in securing examinations, treatment and care. Also \$20,499.77 for Special Campaigns of Information—On tuberculosis among youth, Philadelphia Tuberculosis Conference, institutes, courses of instruction of health workers, and other activities. Follow-up in the control of cancer.

#### EDUCATIONAL MATERIAL

All new educational material and revised editions issued from national sources will be noted in this column if samples of the publications are sent to the editor. That most issues from some sources have been omitted is due to our inability to secure the material.

Possibly we who mention United States Government publications should remind our readers that unused postage stamps will not be accepted by the Superintendent of Documents or any other government office.

Also we might well remind our readers that most government publications may be secured free upon application to a senator or representative. State and local associations could make a point of emphasizing this opportunity.

Mothers and others may be encouraged to write for the popular government publications, with printed or mimeographed memoranda giving titles and addresses for sending their requests. Before preparing such material it may be well to write to the respective senators or representatives to learn if they will supply them to individuals.

Incidentally, all publications from whatever source should be examined before recommending them to others. Some are too out of date for use; others may not be useful to certain groups.

The official address for most government publications when cash is sent: Superintendent of Documents, Washington, D. C. It is *not* necessary to complicate the address by adding "Government Printing Office."

Foods and Cooking, Supt. of Documents, Washington. *Free*. Revised edition of classified list of government publications.

Ask the Life Extension Institute, 25 W. 43d St., New York, if you wish to receive a goodly succession of printed and letter arguments favoring the health examination.

A Survey of the Medical Facilities of the State of Vermont, by Allon Peebles; Midwives, Chiropodists, and Optometrists: Their Place in Medical Care, by Louis S. Reed; The Amount of Life Insurance in the United States, by Mary Dublin. Committee on the Costs of Medical Care, 910 17th St., N. W., Washington. *Free*.

The next three titles are supplied *free* by Metropolitan Life Insurance Co., New York. This group of publications

is free from confusing ornament, but we regret that they are not dated.

Milk—An All-Round Food. Gives briefly and simply the facts about milk as a valuable food and cautions against using unsafe milk. It replaces "All About Milk." 8 pp.

Yesterday and Today. This new rebus for children about diphtheria prevention tells a story of two children who lived 70 years ago and two who live today. It takes the place of "The Prize Winner." This folder should help keep children smiling at the diphtheria clinic and interest them in being protected against diphtheria.

Standing Up to Life. Gives in combined and condensed form information that was contained in the two pamphlets, "Importance of Posture" and "Foot Health." 12 pp.

The Healthy School Child: What Parents Should Know About School Health Work. John Hancock Mutual Life Insurance Co., Boston. 12 pp. *Free*.

It is most important that parents not only know something of the health work the schools are doing, but that they realize how much this service means to the welfare of their own children, if home and school are to work in harmony in building a race of sturdy American youngsters.

I Give and Bequeath, Buffalo Tuberculosis Assn., 708 Ellicott St., Buffalo. 6-large-page folder, one of the few from health agencies setting forth why a health agency is desirable for mention in wills; warning against giving "for a narrowly prescribed purpose."

Books: Interesting Helpful And New, Public Health Center, Oakland, Calif., is a simple but effectively planned mimeographed folder. Send 2 cents for a copy.

New list of publications; More Milk Smaller Bills (5 pp., revised). Evaporated Milk Assn., 203 N. Wabash Ave., Chicago.

## BOOKS AND REPORTS

**Tables of Food Values**—By *Alice V. Bradley*. Peoria, Ill.: *The Manual Arts Press*, 1931. 127 pp. Price, \$2.00.

This book of tables on food values is a welcome contribution to the literature on nutrition. It is divided into 2 parts; in the first are average servings, and in the second, 100-gram portions of commonly used foods. The headings of the tables, besides the measures and the weight, give the protein, fat, and carbohydrate weight in grams, the total calories, and the mineral shares and value as content of vitamin A, B, C, D, and E, the value as a source of bulk, and the acid or basic reaction of the ash, of all foods. With composite foods, like hash, pies, pastries, puddings, salads, sauces, and dressings, the recipes are written out. In the fore part of the book the sources of information, an explanation of the tables, the functions and sources of various food principles, and the method of using the tables are described. The book fills a long felt want, and should be indispensable for physicians, dietitians, and nutrition workers.

FRANCIS L. BURNETT

**Approved Laboratory Technic. Clinical, Pathological, Bacteriological, Serological, Biochemical, Histological**—By *John A. Kolmer, M.D., and Fred Boerner, V.M.D., assisted by C. Zent Garber, M.D.* London: *Appleton*, 1931. Price, \$7.50.

This volume has been prepared by the authors under the auspices of the American Society of Clinical Pathologists with the object of establishing standards for the performance of lab-

oratory examinations and to secure a wider application of clinical laboratory methods to the diagnosis of disease.

While the technic of the methods has been approved by the American Society of Clinical Pathologists, the particular methods have been chosen by the authors. The book is apparently intended for medical technicians, and the methods are given in such detail in most cases that a novice would have no difficulty in using them, yet in other cases certain details are lacking. Some of the approved methods described apparently are those in use in the authors' laboratory, while in some cases more satisfactory procedures used in other laboratories are not given. For instance, the incision in the heart in order to insert a pipette for making blood cultures probably has no advantage over the simpler method of inserting a sterile capillary pipette through the seared surface.

The book is divided into 5 sections, treating respectively of general laboratory, clinical pathological, bacteriological, serological and clinical methods. The first section includes chapters on the microscope and methods of micrometry, but omits what is considered to be a most accurate method of measuring small objects—the use of the Filar micrometer. Chapter III gives in detail routine and special laboratory procedures for examinations of different body fluids or discharges.

The section on clinical pathological methods is carefully done for the most part. A statement of the accuracy to be expected in counting blood cells would be helpful to the technician. The reporting of negative information as well as positive findings is emphasized.

The procedure for the benzidine test for blood seems to be unnecessarily repeated on pages 137, 172, and 200. The chapter on methods for the examination of urine is well illustrated, while that on feces gives some very useless illustrations, such as the mixing and straining of feces. The method described for the bacteriological control of wounds gives only a relative measure of the bacterial content, though, as originally designed, it attempted to control the quantity of material and the area over which it was spread, two points which are omitted.

Section III gives many procedures in common use as well as others not commonly used at present. The technic for prostatic massage is left to be developed by the laboratory worker. A somewhat cumbersome method of plugging test tubes by crossing long fibered cotton is described.

For the preparation of media, very cumbersome and seldom used methods for the determination of pH are described, including the use of litmus paper and the titration with phenolphthalein as an indicator. In the description of a method for the colorimetric determination of hydrogen ions, it is difficult to understand why the authors chose the Sorensen buffers instead of the easily prepared and stable primary phosphate-sodium hydroxide buffers of Clark and Lubs, which cover essentially the same range of pH. In describing a cumbersome and indirect method of adjusting the reaction of media, the authors vaguely hint at some change in the alkali-binding power of a medium as a result of heating, and use this as an explanation for the need of boiling the mixture when phenolphthalein is used as an indicator. These same buffers are said to interfere with the calculation of the amount of acid or alkali which must be added to a medium to secure a desired pH. An approved technic in many other laboratories where large

quantities of media are to be titrated at different times is the use of a titration curve by means of which the amount of alkali necessary to bring any stated amount of a batch to any desired pH can be easily calculated.

On page 303, the method for streak plates in which only 8 to 10 streaks per plate are made involves the waste of at least half the plate. The authors have apparently missed the point in the use of the McIntosh-Fildes method for cultivation of anaerobes, for the mere presence of an electrically heated coil does not cause an increased oxidation of the hydrogen to water. They obtained the method from Wadsworth's *Standard Methods*, which points out that the catalytic agent, spongy platinum or palladium, is necessary to increase the rate of this oxidation. The approved technic for the acid fast stain, page 312, requires heating of the carbol fuchsin until a precipitate forms. This is what most laboratory workers try to avoid. Diphtheroid bacilli are said to show few if any granules when stained by Neisser's method, which is not the fact in most cases. Ponder's stain, considered by many to be a very useful one for staining granules, is not mentioned, nor is Dorner's stain for spores included in this book of "approved" technic.

The vanillin test for indol, though not recommended by the Society of American Bacteriologists, has the stamp of approval of the authors.

One of the best chapters is on bacteriological diagnosis. The regional distribution of bacteria and other pathogenic organisms is tabulated. On page 329, *Sporotrichia* and *Blastomycetes* are placed in the Gram negative groups, though correctly listed on pages 328 and 332. The chief deficiency in this chapter is in the methods for the diagnosis of fungus infections. No mention is made of animal inoculation for the diagnosis of sporotrichosis. The use of potassium hydroxide in the

preparation of material for the examination and culture of actinomyces is not mentioned.

The remainder of the book, including the sections on serological and clinical methods, is extremely useful and up to date.

Though some of the methods are not what might be considered "approved" in other laboratories, this does not detract from the usefulness of the many others given. If the book should serve only to bring about more uniformity in the use and reporting of laboratory procedures, its place would be well earned.

NEWELL R. ZIEGLER

The Right Honourable Sir Thomas Clifford Allbutt—*A Memoir*—By Sir Humphry Davy Rolleston. London: Macmillan, 1929. 314 pp. Price, \$6.00.

The author rightly characterizes this book as the "life of a great personality," undertaken at the request of Lady Allbutt. He speaks of the difficulties due to the fact that Sir Clifford Allbutt kept very few letters, no diary, left no unpublished reminiscences, and few of his contemporaries are still living.

It is fortunate that Sir Clifford Allbutt was so well known and that he had written so much on medical subjects, and one can hardly credit the author's estimate of the difficulties in view of the excellent work which he has given us. Sir Clifford Allbutt was always a student and made records of his careful observations, which were contributed to a number of leading medical journals. In this country his contributions were well known and his *System of Medicine* especially so. He was always a stickler for good English, including correct pronunciation. It is a safe guess that his book, *Notes on the Composition of Scientific Papers*, is on the desk of every careful medical editor in this country. His book was one of the first of its kind

and others have followed it more or less closely. It remains the standard.

To those who had the great privilege of knowing Sir Clifford personally, this book will be a delight. While he could at times be austere, he was in general a most delightful companion and always the courteous gentleman. With Lady Allbutt, he dispensed at his home in Cambridge a hospitality which those who were fortunate enough to partake of it can never forget. His acquaintance in America was wide, not only through visits, but through entertaining Americans in England.

The make-up of the book is all that could be desired. One feature we commend particularly to the writers of biographies. In the margin, even with the top line of each page, the date is given, in addition to which each year is given as a heading. The style of the author, in addition to its accuracy, is most pleasing. The reading is not only easy, but a pleasure, and on every page one meets either medical friends or those with whose work or writings he is familiar. We commend the book to all, and especially to those interested in the history of medicine and medical men.

MAŽECK P. RAVENEL

The Black Death and Men of Learning—By Anna M. Campbell. New York: Columbia University Press, 1931. 210 pp. Price, \$3.00.

The first third of this little book is a good summary of the more detailed studies which have been made of the 16 plague tractates published between 1848 and 1850. It gives an interesting picture of 14th century opinion with regard to the general causes of the disease (astrological) and the more immediate causes (corruption of the atmosphere). Several of the authors emphasize infection also—particularly one of the Arabic authorities, in spite of the fact that the Mohammedan religion frowned upon this theory. Ibn al-Khatib says:

But it belongs among evident principles that a demonstration evolved from tradition, if it is opposed to the perception of the mind and the evidence of the eyes, must necessarily be subjected to explanation or interpretation. And this, in the present instance, is exactly the idea of many who defend infection.

"The physician of Montpellier" (to whose theories Professor Campbell does not perhaps do full justice) also emphasized the importance of infection.

The last two-thirds of the book is devoted to a discussion of the effect of the Black Death upon the medical profession and the universities. Professor Campbell concludes from some rather fragmentary studies of the vital statistics of small groups that about a third of the intellectual leaders of Europe perished in the epidemic. The universities were very seriously crippled for a time but during the latter half of the century vigorous efforts were made to reestablish learning in its necessary place. One result of the pressure which followed these terrible years was the beginning of a breakdown of the barrier between medicine and surgery and an improvement in the practice of the latter art. The practice of postmortem examination was also greatly stimulated.

To the public health worker perhaps the most interesting material is found on pages 112-119 which traces out the evolution of regulations for isolation and quarantine. In 1348 preliminary steps of this kind were taken in Venice, Florence, Lucca and Pistoia, long before the measures taken by Venice in 1374 and by Ragusa in 1377 which have been commonly cited as the beginning of modern quarantine.

C.-E. A. WINSLOW

**Market Milk.** (2d ed.) By Ernest Kelly and Clarence E. Clement. New York: Wiley, 1931. 480 pp. Price, \$4.50.

The first edition of this book is dated 1923. The rapid changes in milk plant practices and improvements in milk

handling machinery during recent years have led the authors to make a general revision of their work. Changes have been made in tables, illustrations, and the text which tend to bring the work up to date.

The authors have drawn freely from valuable data compiled by the U. S. Department of Agriculture, with which department they are connected. Their extensive practical field experience in market milk problems also adds to the value of this work.

A point of passing interest is the use throughout of the term "treated to kill bacteria" in place of the word "sterilized," in referring to what is commonly called the "sterilization" of dairy and milk plant utensils, equipment and containers.

This revision has materially increased the value of this book as a text or source of general information on the handling of milk during its passage from farm to market.

W. D. TIEDEMAN

**The Care and Feeding of Adults with Doubts About Children—**By Logan Clendening. New York: Knopf, 1931. 317 pp. Price, \$2.50.

This delectable book differs from most of the many tomes on personal hygiene in that it is always diverting and entertaining. The fact that all or most of the material has appeared in such sophisticated magazines as *The American Mercury* and *The Forum* guarantees its readability. The fact does not, however, assure its scientific reliability, and there is much in this book to cause a raising of eyebrows by the orthodox sanitarian.

Although this slightly vertiginous book demonstrates that hygienic information for the layman need not be dull, its very cleverness and its highly disputatious character obscure somewhat the really valuable message in it, which is not to make a fetish of any one aspect of personal hygiene. With this attitude

all progressive sanitarians will agree, but not many will concede the elaborately presented arguments of the author that health examinations for adults serve no useful purpose, that exercise is generally baleful, and that the new knowledge of nutrition is something to be ignored.

In a similar iconoclastic spirit, the author discusses clothes, tobacco, alcohol, sleep, diet, meat, salt, and reducing methods, and he gives vent to serious doubts about modern child care, birth control, sex, and psychology. All of it is written in a sparkling and good humored, if somewhat reckless, manner. There is a rather unfortunate chapter on nursing care, consisting mainly of extensive quotations from Dickens and Ring Lardner.

Every sanitarian will enjoy the book. It is heretical, but skepticism and argument never do much harm when tolerantly considered. The layman will also read it with zest and no doubt will derive profit from doing so. The book is admirably printed, as might be expected from its publishers. On the whole, it is to be recommended as a vivacious contribution to popular health instruction.

JAMES A. TOBEY

### Labor Agreements in Coal Mining

—By Louis Block. Foreword and Preface by Mary Van Kleeck. New York: Russell Sage Foundation, Sept. 14, 1931. 513 pp. Price, \$2.00.

The author, who is statistician with the department of industrial relations of California and was formerly with the Russell Sage Foundation, has sub-titled the present volume, "A Case Study of the Administration of Agreements between Miners' and Operators' Organizations in the Bituminous Coal Mines of Illinois."

In the desirability of establishing better cooperation in industry between labor and management, one is not primarily concerned with the conditions

established or the rates of wages or the hours worked, but in the procedures by which the conditions have been brought about and to what extent the voice of labor has been heard in the process. Also, whether or not a procedure has been successful, it should be fully revealed since the ultimate object concerns the interests of the consumer.

"Coal challenges the capacity of all nations to organize its economic life"; the public often suffering because of adjustments made by force consequent upon labor or the employer being temporarily more powerful. Even the 30-odd years of endeavor in Illinois have not resulted in any formula which could be applied for all times without modifications even in Illinois. Yet it has resulted in 99 per cent unionization of miners and almost complete organization of operators, permitting collective bargaining and the keeping of Illinois mining production on a more enduring peace foundation than perhaps anywhere else in the world. The procedures developed in over 10,000 disputes are considered applicable to other industries.

Documentary material and field studies have supplied the basis of the study. The book offers first-hand material for the use of managers in industry, labor officials and students of labor problems—principally upon how disputes are settled in industry upon a day-to-day basis. The conclusion contains the author's summary of the Miners' Code relating to hiring and reinstating, discharging, mine management, wage disputes, and enforcement. The appendices, of 147 pages, contain agreements, constitutions and a chapter on the explanation of terms used in mining. The volume is well written, well printed and, withal, a bargain in price.

Outside of one's curiosity as to the methods of settling labor disputes, the sanitarian will find very little to interest him here. On the other hand he

will be amazed at the lack of all possible reference to health matters in the labor agreements effected despite the Disraelian observation that the wealth of a nation and, we believe, an industry, lies in the health of its people. This, of course, is no fault of the author's. It is simply the *status quo* and suggests to the sanitarian the question of how to interest the great unions and operators' organizations in a basic fundamental of labor disputes and of wealth, i.e., health.

A report upon the Health of Illinois Coal Miners written by the reviewer, though now somewhat old, may be found in the *Report of the Health Insurance Commission of the State of Illinois*, 1919, pp. 376-402.

EMERY R. HAYHURST

**Annual Report of the Surgeon General of the Public Health Service of the United States for the Fiscal Year 1931.** *Washington, D. C.: U. S. Government Printing Office*, 1931. Price, \$.85

This report is, as usual, full of information of the most interesting character. It agrees with the opinion of the Metropolitan Life Insurance Company that 1931 was an unusually healthy year, which is somewhat surprising, considering the depression and drought, the first of which has affected practically the whole country and the second a large area.

The presence of smallpox is still a blot on our record, though 7 states reported no cases. There was a mild outbreak of influenza during the first part of 1931, but on the whole the record is good. Perhaps the most disturbing occurrence of the year was the outbreak of infantile paralysis, which was more prevalent than for 3 years past, and especially common on the Pacific Coast, in Louisiana, Oklahoma, and a few of the North Central States, including the City of New York. Fortunately the type was mild and the death rate as

well as resulting deformities was low.

Tuberculosis reached a new low, 68.5 per 100,000. In 1900, the rate was 201.9 per 100,000. The difference represents the saving of more than 160,000 lives.

Typhoid fever, which has been a diminishing disease, showed some increase in 1930. In certain states this could be traced to drought conditions and the necessity forced on farmers of taking water from unprotected streams and springs.

Both the case and death rates for diphtheria were the lowest on record. Pellagra on the other hand showed a slight increase, which was expected, and in some states seems to have been due to drought conditions, and resulting poor diet.

The great increase in aerial navigation has brought a new problem to our Service. The Surgeon General has taken part in discussions in Paris, looking to the prevention of importation of disease through infected animals and insects. Excellent experiments have been carried out by officers showing that mosquitoes can be brought from infected ports in the tropics to the United States. Other experiments in this connection concerned the rat proofing of vessels and the use of new, or new forms of old disinfectants.

The report asks for increased facilities to aid in the prevention of disease, including laboratories and personnel. Many other points of interest too numerous to mention in a review are discussed. On the whole, the report is one with which every health officer and sanitarian should be familiar, and it can be commended also to the general profession and the public.

MAZÛCK P. RAVENEL

**The Doctor Explains—By Ralph H. Major, M.D.** *New York: Knopf*, 1931. Price, \$3.50.

This book is another of the crop of

books written by physicians for the instruction of the public. The statements given are, as far as we have detected, correct and authentic. We believe that there is too much history compared to the common facts which would be of value to the non-professional public.

Some of the chapters have headings which do not at all fit. For example, No. VI, "The Dangers of Sugar," is devoted to diabetes, and does not consider the use of sugar in the diet, which, in our judgment, would be of more use to the public than what has been given. The greatest authority on diabetes in the United States does not believe that the eating of carbohydrates produces diabetes.

The style of writing does not hold the reader's attention. The make-up of the book is excellent, and the illustrations are good.

MAZÛCK P. RAVENEL

**Health Protection for the Preschool Child**—By George Truman Palmer, Dr.P.H., Philip Van Ingen, M.D., and Mahew Derryberry. *A publication of The White House Conference on Child Health and Protection.* New York: Century, 1931. 275 pp. Price, \$2.50.

This is one of the most illuminating reports resulting from the White House Conference. It represents an enormous amount of work in the collection of data and administration and computation of results. Those who heard Dr. Palmer give his excellent report at the Conference were much impressed by his graphic presentation and the lessons he drove home on the need for more extensive use of the preventive medical and dental facilities available in many cities and rural communities.

The report attempts to determine the extent to which advantage is taken of the preventive medical and dental services throughout the country. A house-

to-house canvass, made by local representatives of nearly 1,000 different organizations, reached approximately 146,000 children in three-fourths of all cities over 50,000 population, and 37,000 children in rural areas of 42 states.

It begins with an excellent summary of the status of preventive measures. A complete and detailed analysis in tables and easily read charts is a revelation of what is being done—and not done—in those measures which we know to be effective for preserving the health of the preschool child. It forms a valuable addition to our knowledge of the status of the preschool child in the United States of America. The book is beautifully printed and bound.

RICHARD A. BOLT

**Medicine in Virginia in the Eighteenth Century**—By Wyndham B. Blanton, M.D. *Richmond: Garrett and Massie, 1931.* 449 pp. Price, \$7.50.

A scholarly and exhaustive study of medicine, dentistry, and pharmacy in Virginia in the 18th century. The author has made a detailed search of the material available regarding this most interesting period of American history, and presents a vivid and well documented story of the time.

Particularly interesting are the chapters on Plantation Medicine, Revolutionary Medicine, and Washington's Physicians, Diseases and Death. The book is excellently printed and substantially bound. A. W. FREEMAN

**The Nurse's Medical Lexicon**—Edited by Thomas Lathrop Stedman, M.D. *New York: Wood, 1931.* 629 pp. Price, \$2.00.

While naturally based on Dr. Stedman's larger work, *Stedman's Practical Medical Dictionary*, *The Nurse's Medical Lexicon* is not a mere abridgment but a very complete dictionary of au-

thoritative information adapted to the needs of any nurse at any stage of her career. Clear, concise definitions and pronunciations are given for thousands of terms used daily in medicine, surgery, obstetrics, dentistry, bacteriology, anatomy, materia medica, nursing, and hospital management. The definitions are so clearly stated that those with little or no technical knowledge will find them helpful.

A well arranged appendix gives both metric and apothecaries' weights and measures in comparative form as well as comparative temperature scales. A list of poisons and antidotes and a timetable of infectious diseases add to the practical value of the book.

From the viewpoint of a public health worker the definitions which have to do with terminology of public health are somewhat inadequate.

The pages of thin paper, with small but easily read print, are bound attractively in flexible leatherette. The book is of convenient size and easily handled. It should be readily available for every nurse as well as for any person who has frequent occasion to use scientific terms.

VIRGINIA A. JONES

**Protozoan Parasitism of the Alimentary Tract. Pathology, Diagnosis and Treatment—By Kenneth M. Lynch. New York: Macmillan, 1930. xvii + 258 pp., 37 figs. Price, \$3.75.**

This book is the product of years of experience in a part of the United States where intestinal parasitism is not unknown, and the outgrowth of contacts with the problems of parasitology of the digestive tract which only a well ordered and busy clinical laboratory can give. Dr. Lynch has been the go-between in the fields of protozoölogy and medicine over a period of reorganization and progress during which new data as to the extent and variety of the protozoan infections of the human digestive tract

have been revealed, on the one hand by stool examinations, and on the other by the study of tissues from autopsies. In these two fields Dr. Lynch has been both pioneer and collaborator with the practitioners. His book is therefore peculiarly valuable as interpretative of microscopical findings for the physician.

The book contains a discussion of morphology, life history, and occurrence of the principal protozoan parasites found in the human digestive tract, discusses dissemination and prevention of infection, and gives methods for treatment. As in the case of many pathogenic bacteria which may be present in the host without the well known catastrophic results, so also the parasitic protozoa may occur without, at the time of detection, being associated with the usual clinical signs of disease. Perhaps the greater certainty of detection of intestinal protozoans, by reason of their larger size, common habitat, and the prevalence of mixed infections, still further tends to confuse the opinions as to their pathogenicity. It is still quite possible that in certain complexes of conditions they may play very different rôles from those played in other complexes. The author is quite correctly conservative about expressing any far-reaching opinions on these matters, but his book will do much to stimulate inquiry and to aid the inquiring physician and clinical laboratory worker to widen the horizon of his interest and knowledge of this all-too-little tilled field.

C. A. KOROID

**The Story of Medicine—By Victor Robinson, M.D. New York: Albert and Charles Boni, 1931. 527 pp. Price, \$5.00.**

The author opens with a dedication of his work to Sir Ronald Ross in which he points out that "the wittiest of Romans, Horace and Juvenal, mocked the mosquito-net—and the mosquito

that strikes by twilight chanted its triumphant hymn amid the ruins of man's greatest empire." Consecutive chapters treat of the advancement of medicine from the Stone Age to the present, the last being devoted to "Medicine in America." Some 20 pages are given to biographical notes which are well selected and criticised. A good index follows.

Most of the volume deals with the progress of scientific medicine, but considerable space is given to magic, superstition, and quackery. Entirely too much space has been devoted to the gruesome story of the body snatchers and several pages are given to the murders committed by Burke and Hare. We cannot agree with the author that the details of this story belong in a history of medicine written for the public, even though, as he claims, Burke "in 9 months of murder accomplished more for anatomy than all the anatomical teachers in the British Isles." Physicians, of course, are interested in the history of how dissection of the human body was opposed, necessitating the stealing of bodies from their graves, and leading in some cases to murder to supply the demand. The stories have value in showing what doctors have had to contend with. For example, the Royal College of Surgeons in London petitioned against the legalization and regulation of the supply of subjects for dissection, in spite of the fact that a number of great physicians worked for it. The Archbishop of Canterbury, with his tremendous religious and political influence, also refused to recognize the needs of anatomy, and the House of Lords would not even consider the matter. It was not until 1832 that anatomy became a legitimate study, and the body snatcher ceased to exist.

Somewhat the same type of criticism attaches to the author's story of medicine in Rome and Greece. We find

there sketches of the lives of the Caesars which are revolting in almost every detail. The reviewer has gone over a number of the leading histories of medicine written for the profession and as history, and fails to find such subjects discussed. Just why these stories, ending with that of Caligula, should be given in a volume for the public, we fail to understand.

It behooves a historian above all others to be accurate in his statements of fact. The last pages of the book, devoted to American contributions to medicine, are eloquent though perfervid. In his zeal to show what America has done, the author has been led into making claims which cannot be substantiated. He claims for America the discovery that typhus fever is carried by the body louse, though the credit belongs to Nicolle and Conseil, 1909-1910. In the same section, he gives to Noguchi the credit for the discovery of the germ of yellow fever. To use his own language in speaking of Sir William Osler's inclusion of Bishop Berkeley among the "Foremost Contributors" to medicine, this blunder "is inexcusable."

The history of the use of ether as an anesthetic is given at some length and correctly, including the discussion which followed as to whom the credit belonged—there having been four claimants—and the story of Oliver Wendell Holmes, who, when asked to decide, made the witty answer, "To e(i)ther"; yet later in the book the statement is made that "from the Massachusetts General Hospital first arose the vapor of ether that has spread like a benediction over the earth." It would be only fair to mention that chloroform was discovered independently by Liebig, Soubeiran, and Guthrie, all in 1831, instead of giving the credit to Guthrie alone.

The book is well written. Every page fascinates. It gives an intimate discussion of many of the personages of

the past, and abounds in quotations which have come down to us as epigrams and adages. In general, we believe that the book is better fitted for the medical reader than the public, as few physicians, outside of those especially interested in medical history, care to wade through ordinary historical texts, filled, as they often are, with dates and devoid of anecdotes. The printing and general make-up of the book are excellent.

MAZŮCK P. RAVENEL

*L'Hygiène Sociale de l'Enfance* (Health Measures as Applied to Children). *Dr. G. Bannu. Published by Association Internationale pour la Protection de L'Enfance. Brussels, 1930. 1st vol. 717 pp.*

The author, who is a physician in Bucharest, Rumania, and who is actively interested in health work for children, published his report under the auspices of the International Association for the Protection of Children. The book seems to be the most complete account in a foreign language of the theory and practice of infant and maternal health work in a number of countries published in Europe in recent years.

An introductory discussion of eugenics and heredity is followed by a long section on maternal hygiene, which includes the pathological and social factors affecting maternal mortality and its causes and prevention. Statistics on maternal mortality for various countries are also given.

Under the heading "Aid to Mothers" is given a detailed account of medical attendance and various other forms of aid provided for expectant mothers and young mothers of small means in institutions or in their own homes; the work

of mothers' mutual aid societies and of family allowance funds is also discussed. A separate chapter consists of brief statements on the maternal health work in 18 countries, including the United States, and another chapter is devoted to legislation on maternal welfare in a number of countries.

Under the problems of infancy the author takes up physiology, pathology, and growth, and infant hygiene. Particular emphasis is placed on breast feeding, but other methods of feeding are also described.

The author is of the opinion that protection of infant health is primarily the duty of the State. The State should devote its attention not only to mothers without means but also to well-to-do and educated mothers, because they, too, need advice on the proper care of their infants and themselves. Among the various agencies for infant and maternal welfare work the author describes infant health centers in the cities, traveling health centers in rural districts, the work of the visiting nurse, benefits paid to mothers who nurse their own children, mothers' mutual aid societies, maternity homes, and day nurseries. In treating his subjects, the author illustrates the conditions in different countries. In addition, a chapter is devoted to the work done in eight countries, also by the international organizations, such as the Health Section of the League of Nations, the League of the Red Cross Societies, the International Association for the Protection of Childhood, and a few others. Summaries are also given of the legislation in nine countries, including the United States. The last part of the report deals with international statistics of infant mortality and its causes.

IRA V. HISCOCK

# A SELECTED PUBLIC HEALTH BIBLIOGRAPHY WITH ANNOTATIONS

**Influenza Statistics**—A wealth of findings is recorded in this summary of the statistical survey of the 1918-1919 influenza pandemic. There seemed to be no geographical difference in incidence, which generally was highest among the very young. The complicating pneumonia caused most deaths among young adults.

BRITTEN, R. O. The Incidence of Epidemic Influenza 1918-1919. *Pub. Health Rep.*, 47, 6: 303 (Feb. 5), 1932.

**Anti-Health Education**—The Health educator has not only the work of the quack and the nostrum vendor to undo, but occasionally he must rid the health educational machinery of the monkey wrenches thrown into it by the writers who will give editors anything the latter think the intelligentsia would like to read. This paper is an excellent example as its title suggests.

CLENDENING, L. The Myth of the Magnificent Brute. *The Forum*, Mar., 1932, p. 181.

**Smoke Abatement**—The story of the Schenectady plan for discouraging smoky chimneys. Fire inspectors were used successfully and economically.

COHN, M. "Where There is Smoke—" *Munic. San.*, 3, 2: 60 (Feb.), 1932.

**Esthetic Sewage Treatment**—Modern plants in which sewage is treated without violence to the noses and eyes of nearby dwellers are described and pictured to prove that it can be done.

DONNIS, P. N., and CARLEN, C. H. Camouflaging Sewage Treatment Plants. *Sewage Works J.*, 4, 1: 91 (Jan.), 1932.

**County Health Work**—The principles of rural health administration are presented clearly and convincingly in

this excellent summary of the much discussed subject.

FREEMAN, A. W. Rural Health Administration. *Pub. Health* (Michigan Dept. of Health), 20, 1: 3 (Jan.), 1932.

**Scarlet Fever Isolation**—Provocative indeed is this excellent inquiry into the effectiveness of quarantine regulations. Instead of suggesting a uniform, nation-wide code as some sanitarians have appeared to advocate, the author points out the clinical differences in patients that prompt individual considerations of each case in evaluating communicability.

GORDON, J. E. Epidemiology of Scarlet Fever. *J. A. M. A.*, 98, 7: 519 (Feb. 13), 1932.

**Fighting Pneumonia in Massachusetts**—Telling of the threefold, epidemiologic, immunologic, and case-study project against pneumonia. The results are summarized with the statement that the mortality rates among the patients treated under the state scheme are half the expected rates, a very good showing.

HEFTRON, R. Massachusetts Pneumonia Program. *New Eng. J. Med.*, 206, 7: 328 (Feb. 18), 1932.

**In Praise of Toxoid**—Written for nurses, this review of the advantages of toxoid as the immunizing agent against diphtheria will prove an excellent reference paper for all health workers.

KNOWLTON, M. Toxoid the Next Step in the Conquest of Diphtheria. *Pub. Health Nurs.*, 24, 2: 73 (Feb.), 1932.

**Food and the Eyes**—"Evidence is set forth showing that one of the most constant signs of food deficiency is the pigmentation of the conjunctiva and the reduction of the light sense." So

begins the summary of an important contribution to the subject of nutrition.

LANE, L. A. Practical Points of Ophthalmic Practice. J.A.M.A., 98, 9: 726 (Feb. 27), 1932.

**For Dairy Bacteriologists**—The geometric mean is a more nearly correct average than the arithmetic mean over a normal distribution of bacterial counts of market milk: the latter is unreliable.

ROBERTSON, A. H. Averaging Bacterial Counts. J. Bact., 23, 2: 123 (Feb.), 1932.

**School Child Health Administration**—"The following discussion was prepared primarily with a view of at-

tempting to interest the school physician in the entire field of school health education," begins this article which will interest a great many other health workers as well.

SUNDWALL, J. Health Education and the School Physician. School Physicians' Bull., 2, 1: 6 (Jan.), 1932.

**Diluting Schick Test Toxin**—Diphtheria toxin diluted with aqueous solution of peptone, sodium chloride and phenol retains its toxicity satisfactorily.

WHITE, B., *et al.* An Improved Diluent for Diphtheria Toxin in the Schick Test. J. Immunol., 22, 2: 93 (Feb.), 1932.

# NEWS FROM THE FIELD

## SURVEY OF HEALTH EDUCATION ACTIVITIES

THE first comprehensive survey of health education activities in Boston is being undertaken. This study will include the activities of the Boston Health Department, the schools, city medical institutions, private agencies, and commercial groups. The work will be carried on under the supervision of the health education committee of the Boston Health League, of which Clair E. Turner, Professor of Biology and Public Health at the Massachusetts Institute of Technology, is Chairman.

## COLORADO STATE NURSES MEET

THE Colorado State Nurses' Association met at Pueblo on February 11 and 12. Eleanor L. Kennedy, of the State Bureau of Public Health, addressed them on New Mexico's public health organization and the way public health nurses are secured and kept in touch with the latest developments in public health.

## WESTERN BRANCH A. P. H. A.

THE Western Branch Meeting in Denver will be from June 9 to 11. The subjects which western speakers will discuss will include: Consolidation of All Health Services in One Department; Local Health Councils; The Difficulties of Botulism Control in High Altitudes; Diphtheria Immunization; Potability of Farm Water Supplies; The Cause and Prevention of Mottled Enamel (a drinking water problem); Sanitary Control of Shellfish; Relapsing Fever; Health Values of a State Dairy Council; Adult Health Education; The Denver Infant and Maternal Mortality Study; Qualifications of Public Health

Nurses; Generalized Public Health Nursing from the Health Officers' Standpoint; Public Health Nursing Education; Teaching Hygiene to Teachers; The A. B. C.'s of Vital Statistics; A State Mental Hygiene Program; Psittacosis; Coccidioidal Granuloma; Trichinosis; Silicosis and Its Relation to Tuberculosis; and others.

## NATIONAL TUBERCULOSIS ASSOCIATION

IMMEDIATELY preceding the meeting of the Western Branch A. P. H. A. the National Tuberculosis Association will hold its Twenty-eighth Annual Meeting at Colorado Springs, Colo. The dates for this meeting are June 6-9. The program is to be in four sections—Pathological, Clinical, Sociological, and Administrative.

## WORK OF CHILD HEALTH CENTERS IN MEXICO CITY

THE first child health center in Mexico was established by the National Department of Health in 1922 in Mexico City. By the middle of 1931 the number of such centers reached 14 in the Federal District alone, which includes a small territory in addition to Mexico City. These centers, under the supervision of the National Department of Health, give free examination to expectant mothers and children under 2½ years of age and advice on the care of health. In some cases, sick children and women are also treated. Visiting nurses assist the physicians at the centers and follow up the mothers and children in their own homes. In 1930, nearly 6,700 expectant mothers and 11,000 children made 160,000 visits to the centers.

It was found that the rate of still-

births among the expectant mothers attending the health centers was one-third of the rate among the same women before they attended the centers; the mortality rate of the children under 2½ years of age attending the centers was 4.8 per 100 live births against 28 per 100 such births among those in Mexico City as a whole.—*Revista Mexicana de Puericultura*, Mexico City, 2, 13, 1931.

#### KEYNOTE FOR MAY DAY, 1932

##### General Purpose of May Day, 1932

To focus the spirit of this year—which is a spirit of unselfishness, of sharing, of responsibility toward our neighbor—upon the needs of children in order that

Each child may be sheltered in its own home and share secure family life during 1932

Each child may have the essential food elements in each day's diet during 1932

Each child may have an adequate amount of clean and safe milk in 1932

Each child may have plenty of sunshine, sleep, rest and recreation

Each infant in 1932 may be born healthy, of a healthy mother who will live to love her child and take care of her family

and that all

The nineteen points of The Children's Charter—the Magna Carta of Childhood—may be put into practice in every community.—National Child Health Day Committee of the American Child Health Association.

#### COLUMBIA COURSE IN PUBLIC HEALTH

COLUMBIA University announces a new course in public health, as a part of the Home Study Department. The program consists of 2 courses, one a study of preventable diseases, the other a study of public health administration.

#### NEGRO HEALTH WEEK

THE program for the 18th annual observance of Negro Health Week is being arranged by the Annual Tuskegee Conference and other negro organizations in coöperation with the U. S. Public Health Service, city and state departments of health, and various voluntary agencies. The schedule for the week follows:

Sunday,	April 3....	Mobilization Day
Monday,	April 4....	Home Health Day
Tuesday,	April 5....	Community Sanitation Day
Wednesday,	April 6....	School Health Day
Thursday,	April 7....	Adults' Health Day
Friday,	April 8....	Special Campaign Day
Saturday,	April 9....	General Clean-up Day
Sunday,	April 10....	Report and Follow-up Day

#### HEALTH OF YOUNG WORKERS IN GERMANY

PHYSICAL examination of young workers, which is compulsory in many parts of Germany before the issuance of an employment certificate, is also repeated in some cities at a later date. In the city of Kiel one of the public health physicians examined 424 boys before they entered apprenticeship in various trades and examined them again two or more times during their apprenticeship which lasted from 2 to 3 years.

The results of this study prove in the author's opinion the correctness of the prevailing assumption that the physical development of young workers differs in the various occupations. Although this difference is due in part to constitutional variations and to the fact that stronger boys take up more strenuous work, still, the author finds, the occupation itself produces an effect on the growing body.

The more strenuous occupations seem in general to stimulate growth more than the others. This was particularly noticeable in the outdoor building trades, in which, according to the author, even

boys of medium strength showed in the second year excellent progress in their health and physical development, as revealed by a reëxamination.

Next followed the metal trades, in which the boys engaged in the more strenuous processes showed a better progress of physical development than those in less strenuous work. Among the wood-workers and book binders, improvement was slower, even when the boys were in good health at the beginning of their employment. Still less favorable was the situation among the clerks in mercantile establishments; often boys in these establishments who in the beginning were strong and well developed remained behind the boys in other occupations. Least satisfactory were the results obtained among the apprentices in the clothing trades and the unskilled workers, among whom the degree of physical development during the time of apprenticeship was below the average.—*Arch. f. Sociale Hygiene und Demographie*, Berlin, 6, 5: 329, 1931.

#### NORTHERN CALIFORNIA PUBLIC HEALTH ASSOCIATION

THE annual meeting of the Northern California Public Health Association was held in San Francisco, January 30, 1932. The election of officers was as follows:

President—Dr. Thomas A. Storey,  
Stanford University

President-Elect—Dr. Herbert F. True,  
Sacramento, Calif.

Vice-President—Dr. Wilfred Kellogg,  
Berkeley, Calif.

Secretary—Dr. Walter H. Brown, Palo  
Alto, Calif.

Treasurer—Mary E. Davis, R.N., San  
Francisco, Calif.

#### MILBANK ANNUAL MEETING

THE tenth annual meeting of the Advisory Council of the Milbank Memorial Fund was held on March 16 and

17. Dr. William Henry Welch, of the Johns Hopkins University, formally resigned as Chairman of the Council, a position he had held since its organization in 1922. His successor is Dr. Livingston Farrand, President of Cornell University.

Dr. Ray Lyman Wilbur, United States Secretary of the Interior, delivered an address on the economics of public health and medical care. He presented and commented on some of the main findings of the Committee on the Costs of Medical Care, of which he is the Chairman.

While this was the tenth anniversary of the Advisory Council, the Fund itself is 27 years old, having been incorporated in 1905.

#### MOTHER'S DAY

THE Maternity Center Association, 1 East 57th Street, New York, N. Y., will be glad to help local organizations everywhere to call the attention of their communities to the vital need for adequate maternity care. Mother's Day is Sunday, May 8. Material for speeches, programs for women's clubs, outlines for church services, and other helps for local campaigns are available free of charge to those interested in improving conditions in their locality.

#### LAETARE MEDAL AWARDED DR. MAHER

THE Laetare Medal has been awarded to Dr. Stephen J. Maher, of New Haven, Conn., internationally recognized authority on tuberculosis, by the University of Notre Dame. The medal is awarded annually to an outstanding Catholic layman. Dr. Maher, who is 71 years old, is the forty-ninth recipient of the award.

#### RESEARCH FELLOWSHIPS

THE National Tuberculosis Association announces a limited number of fellowships in social research as related

to tuberculosis, open to graduate students who have had special training in statistics, social science, or public health. Preference will be given to candidates who are interested in pursuing research in public health after the completion of this fellowship.

The fellowship grants will date from October 1, 1932. They are for a 12-month period and the fellowship grant amounts to \$1,200 for that period with a month's leave for vacation.

Candidates should apply to Jessamine S. Whitney, Statistician, National Tuberculosis Association, 450 Seventh Avenue, New York, before June 1, 1932.

#### INFANT MORTALITY LOWEST IN 1930

**T**HE lowest infant mortality rate ever attained by the cities of this country was that of 1930, according to the Statistical Report of Infant Mortality, based on the records of 860 cities in the Birth Registration Area of the United States, just issued by the American Child Health Association. The 1930 rate—62.2 deaths for every 1,000 live births—is 4 points lower than that of the preceding year, when it was 66.2.

#### REVERE, MASS.

**T**HE first organized effort to induce parents of preschool children to have them immunized against diphtheria was launched by Dr. Francis Licata, member A. P. H. A., Chairman of the Board of Health, in March.

#### THOMAS W. SALMON LECTURES

**T**HE first series of the Thomas W. Salmon Memorial Lectures will be given at the Academy of Medicine in New York, beginning April 8. The lecturer will be Dr. Adolf Meyer, of Baltimore, who was chosen by the committee in charge of the lectures in recognition of his services to American psychiatry.

These lectures were established in honor of the late Dr. Thomas W. Salmon, Professor of Psychiatry of Columbia University, and the first Medical Di-

rector of the National Committee for Mental Hygiene.

#### TYPHOID CARRIERS

**T**HE State Health Department has announced that more than 500 persons in the State of New York are listed officially as typhoid carriers. The state's close supervision of carriers is indicated in the fact that only 7 cases of typhoid were traceable to them, 5 carriers being responsible.

#### PERSONALS

**HELEN TEAL, R.N.**, of Kendallville, Ind., is the new Executive Secretary of the Indiana State Nurses' Association, Indianapolis.

**MARY WALSH, R.N.**, of Gary, Ind., who formerly was part-time Executive Secretary of the Indiana State Nurses' Association and part-time Educational Director for the Indiana State Board of Examination and Registration of Nurses, is now full-time Educational Director of the latter organization in Indianapolis.

**DR. J. NORMAN HENRY** was appointed Health Officer of Philadelphia recently. For 17 years he served at the Pennsylvania Hospital, and was at one time clinical professor of medicine at the Woman's Medical College.

**DR. JOHN G. ANDERSON**, of Fayetteville, O., has been appointed Health Officer of Brown County, to succeed Dr. William L. Faul, of Russellville, O., who retired from active service.

**DR. RAFAEL SILVA**, member A. P. H. A., has resigned from the position of Chief of the Department of Public Health of Mexico, to devote himself exclusively to private practice. Dr. Gastón Melo will succeed him.

**CHARLES GILMAN HYDE**, Professor of Sanitary Engineering of the University of California, was recently appointed consulting sanitary engineer to the Director of Public Health of San Francisco, Calif. It should also

be noted that under the new City Charter of San Francisco the title of the health officer, after January 8, 1932, is "Director of Public Health."

#### DECEASED

GEORGE EASTMAN, founder and chairman of the board of the Eastman Kodak Company, internationally known philanthropist and inventor, killed himself on March 14. He was 71 years of age, and was an Honorary Fellow of the American Public Health Association.

#### CONFERENCES

April 4-8, American College of Physicians, San Francisco, Calif.  
 April 11-15, American Nurses Association, San Antonio, Tex.  
 April 11-15, National Organization of Public Health Nursing, San Antonio, Tex.  
 April 11-15, National League of Nursing Education, San Antonio, Tex.  
 April 19-23, 37th Annual Convention of the American Physical Education Association, Philadelphia, Pa.  
 April 30-May 7, Boys' Week.  
 May 9-10, American Association of Medical Milk Commissions, and the Certified Milk Producers' Association of America, New Orleans, La.  
 May 10-15, Annual Congress of The Royal Institute of Public Health, Belfast, Ireland.  
 May 12-13, Annual Pennsylvania State-wide Safety Conference, Harrisburg, Pa.  
 May 15-21, National Conference of Social Work, Philadelphia, Pa.  
 May 25-27, The Canadian Public Health Association, 21st Annual Meeting, in association with Ontario Health Officers' Association, Toronto, Ont.  
 June 2, 3, State and Provincial Health Authorities of North America, Washington, D. C.

June 6-9, National Tuberculosis Association, Colorado Springs, Colo.  
 June 9-11, Third Annual Meeting, Western Branch, American Public Health Association, Denver, Colo.  
 July 21-29, 100th Anniversary Meeting, British Medical Association, London.  
 July 25-30, Regional Conference of the World Federation of Education Associations, Honolulu, Hawaii.  
 July, 1932, International Conference of Social Work, Frankfurt.  
 August 15-18, International Congress for Light, Copenhagen.  
 August 29-September 3, International Congress of Physiology, Rome.  
 September 6-9, International Union Against Tuberculosis, The Hague.  
 October 12-16, 20th Annual Safety Congress and Exposition, Chicago.  
 October 24-27, 61st Annual Meeting, American Public Health Association, Washington, D. C.

#### School of Hygiene and Public Health of the Johns Hopkins University

The fifteenth session begins October 3, 1932

Opportunities for instruction and investigation will be offered in Public Health Administration, Epidemiology, Bacteriology, Immunology, Protozoology, Vital Statistics, Sanitary Engineering, Helminthology, Physiology as applied to Hygiene, Chemistry as applied to Hygiene, Sanitary Law, Personal, Social and Mental Hygiene, etc. Practical work is provided through the assistance of the city and state departments of health and other organizations, and arrangements are made for field work during the summer. Courses are organized on a quarterly basis, each quarter consisting of approximately eight weeks. Students may enter the school as candidates for a degree or as special students at the beginning of any quarter. Men and women are admitted on the same terms.

Courses are arranged leading to a Certificate in Public Health, and to the degrees of Doctor of Public Health, Doctor of Science in Hygiene, and Master of Science in Hygiene. The details in regard to the requirements for matriculation in these courses will be forwarded upon application.

### Intermittency in Growth as an Index of Health Status

C. E. TURNER, DR. P. H., F. A. P. H. A. (*Life Member*),  
ELLEN LYTLE, AND CHARLOTTE WINNEMORE, M. D.

*Department of Biology and Public Health, Massachusetts Institute of  
Technology, Cambridge, Mass.*

CHILDREN in the public schools are commonly weighed each month to observe growth, but their weights are no longer compared with height-weight averages to determine which children are "underweight." The present procedure is based upon studies<sup>1,2</sup> which have shown the limitations of underweight as a health index, and upon experience which shows that the child's interest in watching his growth is a motivating factor in the development of health habits.

It is a recognized fact that growth among healthy children is a reasonably continuous process. What is the significance of intermittency?

We have sought to determine the answers to the following questions:

1. To what extent does intermittency occur among school children in the first 6 grades?
2. Is intermittency in growth usually associated with unhygienic living, physical defects or illness?
3. Can intermittency be used as a method of screening out public school children who need special attention?

Children in 6 of the elementary schools of Malden, Mass., were weighed once a month on the same day each month and at the same time of day, with shoes on, by the classroom teacher. A classroom weight record was kept of each monthly weighing.

In order to determine the amount of intermittency, we examined the records of 971 children, 6 to 12 years (see Figure I). For the school year 1929-1930 we found that 16 children, or 1.7 per cent of

the group, had gained weight each month; 42.1 per cent of the group failed to gain in one or more monthly periods but never failed to gain over a 2-month period; 36.6 per cent failed to gain over one or more 2-month periods but never failed to gain over a 3-month period; 15.4 per cent failed to gain for a 3-month period but never for a 4-month

period; 3.3 per cent failed to gain for a 4-month period but never for a 5-month period; 0.9 per cent of the group failed to gain for 5 months in succession. Figure II shows that the distribution of intermittency for the different ages is approximately the same.

During the last half of the school year 1929-1930 we gathered additional data concerning 95 children (Group I) who had failed to gain for a period of 3 months within the school year. (Eight children in this group gained  $\frac{1}{4}$  pound during the 3 months in question, the others showed no gain or loss.) In September, 1930, we gathered similar data concerning a control group of 100 children in the same schools (Group II) who had gained regularly, that is, children who had never failed to gain over a 2-month period during the preceding school year. Four of these children had shown a gain each month and none had failed to register a monthly gain more than twice.

The present study compares the children who failed to gain over a 3-month interval with those who gained regularly. The information concerning these children was secured from the physical record cards of the school system, and by means of a physical examination to which parents were invited. The scholastic ability of the child was rated by the teacher. At the same time an individual health habit conference took place between a health education worker and the child, and the child's program for the previous 24 hours was reviewed as an index of his health behavior. The nature of the data collected at these conferences may be seen from the form used.

Table I shows some interesting data regarding the nature of these children.

TABLE I  
NATURE OF GROUPS STUDIED

	Group I	Group II
Number of children	95	100
Children of good mental ability	52	55
Children of fair mental ability	23	26
Children of poor mental ability	20	18
Large family (5 or more)	51	59
Families with more than one wage earner	4	12
Children whose mothers work	14	10
Fathers out of work	5	6
Fathers not living	5	4
Mothers not living	2	3
Children working outside daily	7	5
Children working outside one day or more weekly	12	6
Children taking some outside lessons	26	29
Parents present at physical examination	56	56

The distribution of good, fair and poor students was practically identical in the two groups. There was no appreciable difference in the number of parents who attended the physical examinations, in the

 Group II - 1 Mo. or 2 Mo. Intermittency (740 Children).  
 Group III - 3 Mo. or Longer Intermittency (187 Children).

number of children taking lessons of some sort outside of school, in the number of children coming from large families, or in the number of children whose father or mother was not living. There is some suggestion that the children in the consistently gaining group were in somewhat better economic situations because in more cases there was a second wage earner in the family, in slightly fewer cases were the mothers gainfully employed outside the home, and in somewhat fewer cases were the children regularly and gainfully employed outside of school. In short, these two groups of children taken from the same schools seem alike in mental ability, in general home and social conditions, and not greatly different in economic status.

Since the children studied were drawn from a rather wide age group, Table II is inserted to show the distribution according to age.

In gathering information concerning the habits of the children during a 24-hour period, care was taken to avoid any embarrassment on the part of the child in stating frankly what had taken place. Pupils

can remember what they did during 24 hours preceding the conference, and experience has shown that much more accurate data can be obtained in this way than by inquiring what they "usually do." See Table III.

It will be seen that faulty health behavior was much more common in the children who had failed to gain over a 3-month period. In comparing breakfasts we find that Group I showed twice as many children who failed to have milk. The difference in the numbers of children having cereal or bread is probably not significant since one is often a

TABLE III

A COMPARISON OF HABITS BASED ON THE STUDY OF A 24-HOUR PERIOD

	Group I 95	Group II 100
Number of children in group		
Having for breakfast—		
No cereal (egg allowed as substitute)	20	27
No milk or cocoa	32	14

Having inadequate liquid (less than 4 glasses of water and less than 3 glasses of milk)	21	17
Having inadequate milk and no fruit or vegetable	21	6
Having no cereal or bread for breakfast	3	4
	28	11

\* Of this group those who had no milk or cocoa for breakfast were

† These figures are not comparable because the data for Group I were taken in the winter and those for Group II in September.

substitute for the other, and since we find only 3 in Group I and 4 in Group II who did not have either cereal or bread. There is only a slight difference in the number of children who failed to have fruit for breakfast, but 52 in Group I failed to have any fruit during the day, while only 34 in Group II reported such failure. Group I had 17 more children than Group II who received less than 3 glasses of milk, and 15 more who had no source of protein except milk.

When we look up the number of children who had less than 3 glasses of milk and no other protein, we find 13 in Group I and 5 in Group II. We find 29 in Group I who had neither fruit nor vegetables besides potato, but only 14 in Group II. There was no significant difference in the number of children who had tea or coffee, the number who failed to have a bowel movement, or the number who failed to play out of doors. Nearly all in both groups had a satisfactory record in these respects.

Appreciably more of the children who had failed to gain showed inadequate hours of sleep. (Inadequate sleep was based on the following standard:  $11\frac{1}{2}$  hours at ages 6 and 7, 11 hours at ages 8 and 9,  $10\frac{1}{2}$  hours at ages 10 and 11, 10 hours at ages 12 and 13.)

The question of liquid intake is somewhat confused by the fact that some children may substitute milk for water at certain times of the day. In order to determine the number of children having inadequate liquid, therefore, we determined the number who had less than 4 glasses of water and less than 3 glasses of milk, finding 21 in Group I, and 17 in Group II.

In order to secure some index of the number of children having low vitamin intake, we checked those having less than 3 glasses of milk and no fruit or vegetable during the day. There were 21 in Group I and 6 in Group II.

In order to get data on the more serious faults let us compare the children with respect to 5 items of behavior: (1) inadequate protein (less than 3 glasses of milk and no meat, fish or eggs), (2) low vitamin intake (less than 3 glasses of milk and no fruit or vegetables), (3) inadequate sleep, (4) inadequate liquid (having less than 4 glasses of water and less than 3 glasses of milk), and (5) deficient roughage (having neither fruit nor vegetable besides potato). Table IV shows the number in each group deficient in none, 1, 2, 3, 4 or all 5 of these. The number of children in Group I whose health practices were at fault with respect to 2 or more items is 33 as compared with 12 in Group II. The reader may be struck by the fact that 33 of the children who had failed to gain were at fault in none of these particulars. Most of these were suffering from recent illness or from physical defects.

Of course these data do not pretend to present a complete, accurate, and adequate picture of health behavior in the two groups; but they do show a significant difference.

TABLE IV

NUMBER OF CHILDREN HAVING INADEQUATE PROTEIN, VITAMINS, SLEEP, LIQUID OR ROUGHAGE

No. Items Wrong	Children in Group I	Children in Group II
0	33	54
1	29	34
2	18	8
3	8	4
4	5	0
5	2	0
Total	95	100

Table V compares the two groups of children with respect to the number of physical defects sufficiently serious, in the judgment of the examining physician, to require correction or treatment.

TABLE V

PHYSICAL DEFECTS REQUIRING CORRECTION

	Group I	Group II
Number of children	95	100
Enlarged cervical glands	2	0
Posture (drooping)	8	1
Nutrition	4	2
Teeth	49*	48*
Feet	1	1
Tonsils	12	6
Tonsils (corrected)	45*	60*
Scalp	1	0
Sight	0	2
Eyes (not vision)	1	0
Hearing	5	1
Ears (not hearing)	3	2
Skin	4	1
Heart	1	0
Lungs (dullness)	2	0
	44	16

\* Items not included in totals.

It will be seen that there were nearly 3 times as many physical defects in Group I as in Group II. A few items are especially worthy of note. The only defect more common in Group II than in Group I was vision. On the other hand, defects of the lungs, heart, and cervical glands occurred only in Group I, and defects of hearing, skin, tonsils, posture and nutrition were relatively more common among these children whose growth record was poor. The number of cases of seriously defective nutrition was small. The basis of this diagnosis was the judgment of the physician using many indexes, including particularly

the condition of the subcutaneous tissue. If the fallacious practice of diagnosing malnutrition upon the basis of 10 per cent underweight had been followed, we should have recorded approximately 40 such children. It is interesting that appreciably more children in Group II had had corrective treatment for diseased tonsils.

Of course physical defects varied in severity; not every physical defect would interfere with growth; and the same type of physical defect might or might not interfere with the growth of a child according to his health status in other respects, or according to whether or not his mode of living was sufficiently good to allow him to overcome the drain which this defect might put upon the system.

Table VI shows the number of children with 1, 2, or 3 of the above defects.

TABLE VI  
DISTRIBUTION OF PHYSICAL DEFECTS (TOOTH DEFECTS NOT INCLUDED)

Number of Defects	Number of Children	
	Group I	Group II
1	14	12
2	9	2
3	4	0
Total	27	14

Records of the illnesses of these groups of children were secured. For Group I we have data for the 6 months during which the intermittency of growth occurred; for Group II for the 10 months of the school year. Table VII shows that when reduced to the same time basis, the incidence of disease was almost twice as great in Group I as in Group II, while the incidence of common cold was over 4 times as great. The non-communicable diseases or conditions in Group I re-

TABLE VII  
ILLNESSES

	Group I		Group II	
	No. Cases	Av. No. Cases Monthly	No. Cases	Av. No. Cases Monthly
Children studied	95		100	
Months included in study	6		10	
Cases of cold and grippe	28	4.6	11	1.1
Chicken pox	6	1.0	5	0.5
Whooping cough	9	1.5	11	1.1
Scarlet fever	0	0	1	0.1
German measles	0	0	1	0.1
Mumps	3	0.5	8	0.8
Illnesses from non-communicable diseases	9	1.5	11	1.1
Total number of cases	55	9.1	48	4.8

ceiving treatment included tonsillectomy, digestive difficulty, tonsillitis, asthma, swollen glands, and ear trouble, while in Group II they included tonsillectomy, tonsillitis, severe nose bleed, appendectomy, ear trouble, fractured skull, burn.

A disease might or might not interfere with growth according to its severity, the care received by the patient, or the condition of the child in other respects.

We have seen that the children who have gained regularly have a superior record in habits, illness, and physical defects. It seems worthwhile to compare the number of children in the two groups suffering from deficiencies in each of these respects and from combinations of such deficiencies. Table VIII gives the result of such a study.

TABLE VIII  
COMPARATIVE CONDITIONS OF CHILDREN

Health Deficiencies	Number of Children	
	Group I	Group II
None observed	4	17
Defective teeth and one faulty habit only	18	24
Two or more faulty habits only	8	6
Illness only	27	36
Physical defects only	4	9
Poor habits and illness	12	4
Poor habits and physical defects	8	1
Illness and physical defects	8	2
Poor habits, illness and physical defects	6	1
	<hr/> 95	<hr/> 100

It should be explained that the basis of judging habits here is that used in Table IV and the children are divided into habit groups according to whether they are at fault in none, 1 or more of the 5 fundamental health practices mentioned. Considering faulty habits, illness and physical defects, it will be seen that most of the children in Group II suffer from only 1 of these conditions, only 8 per cent of these children being deficient in more than 1 respect, whereas 36 per cent of the children in Group I are deficient in 2 or in all 3.

#### SUMMARY

The extent to which children fail to gain over different periods of time was determined. Weighings would have been somewhat more accurate without shoes. It is probable that because of the more rapid growth at the adolescent period these findings for elementary school children would not apply to those in the junior and senior high school.

Children who have failed to gain for a 3-month period reflect appreciably poorer health habits and definitely lower health status than

those who have gained regularly. Nearly 3 times as many in the former group (33:12) have 2 or more important unhygienic habits; serious physical defects are nearly 3 times as numerous among them (44:16); nearly twice as many (27:14) have such defects; illness is nearly twice as common (9.2:5). The number of children defective in 2 or all 3 of these respects is over 4 times as great (34:8).

Intermittency in gaining weight does not draw a sharp line between the children who seem to need attention and those who do not; but it is more commonly accompanied by departure from normal health than is regular growth. (Obese children usually gain regularly and too rapidly. This screening is not applicable to them.)

There are always differences in the seriousness of the defects recorded and in the vitality of individual children. The relatively few who showed regular gains, although burdened with a combination of unhygienic habits, illness and defects, appear to have had sufficiently good natural vitality or home care to maintain growth in spite of these conditions.

A few children, 4 per cent, showing intermittency for 3 months, exhibited no departure from normal. A somewhat larger group, 18 per cent, showed only minor difficulties. It may be that our studies failed to reveal existing defects, unhygienic habits or departures from normal organic health. It may be that nervous fatigue, worry over school work, or some other unobservable factor interfered with growth. It may be that a few children who are maintaining a reasonably satisfactory state of health show intermittency to this degree.

#### CONCLUSION

Since school children are weighed regularly anyway and since children who have failed to grow for a 3-month period show a much poorer condition in respect to habits, illness and physical defects, it seems worthwhile for the teacher, school nurse and school physician to give them individual attention in order that unhygienic living may be discontinued, complete recovery from illness secured, physical defects corrected, and in order that children needing continuing medical care may be referred to the family physician.

# Meaning of "Antiseptic," "Disinfectant" and Related Words\*

AUSTIN M. PATTERSON, PH. D.

*Antioch College, Yellow Springs, O.*

THE use of technical and semitechnical words in commerce has increased rapidly with the development of research and the growth of advertising. The modern market affords an amazing variety of articles, the manufacture, merits, and use of which are discussed in a voluminous literature.

It is desirable that the scientific terms employed should convey clear meanings to all concerned, or at least not give a wrong understanding. Words do not always have one simple sense. A language is a living, growing organism, and its words take on color, gain fresh content, acquire new senses and lose old ones as the years pass. It is the task of the dictionary worker to discover and set forth the present meanings of words in the light of their history.

In this article definitions and comments are presented for the following terms: antiseptic, bactericidal, bactericide, deodorant, deodorize, disinfect, disinfectant, disinfection, disinfest, germicidal, germicide, insecticidal, insecticide, prophylactic, sterilization, and sterilize.

The conclusions are based chiefly on a study of the more widely disseminated literature in English, especially reference books both scientific and general, but also on conversations and correspondence with physicians, bacteriologists, government officials, manufacturers of chemicals, and laymen.

## GERMICIDE, -DAL

### *Definitions—*

*germicide, n.* Anything that destroys germs (microörganisms); applied especially to agents that kill disease germs.

*germicidal, adj.* Destroying germs; pertaining to germicides.

*Comments—*The word *germ*, in the sense of microörganism, is a popular one, but it has been used in forming the convenient terms *germicide* and *germicidal*, which find extensive use in technical as well as popular literature. There seems to be little disagreement as to the meaning of these terms: a substance is a germicide if it will kill germs and whether or not it will do so can be experimentally deter-

\* The investigation herein reported was conducted with the aid of a grant from the Insecticide and Disinfectant Manufacturers' Association.

mined. As the words are ordinarily used, the germs referred to are those of disease. The chief point of controversy that could arise is with reference to differences in resistance. In practice it is assumed that a substance represented as a germicide, when used as directed, will kill all ordinary disease germs, but is not necessarily required to be capable of destroying bacterial spores. In combating diseases such as anthrax or tetanus, caused by spore-forming bacteria, germicides or procedures specially effective against spores will be required.

#### BACTERICIDE, -DAL

##### *Definitions—*

*bactericide, n.* Anything that destroys bacteria.

*bactericidal, adj.* Destroying bacteria; pertaining to bactericides.

*Comments—*These terms are synonymous in large part with *germicide* and *germicial*, the chief difference being that the two latter are somewhat broader, inasmuch as they may include microorganisms other than bacteria. *Bactericide* is a precise term applying only to bacteria and to bacteria of all kinds; in practice, however, it is ordinarily regarded in the same light as *germicide* with respect to the resistance of different bacteria; that is, a substance, in order to be called a bactericide, is not necessarily required to be capable of destroying bacterial spores.

#### ANTISEPTIC

##### *Definitions—*

*antiseptic, n.* A substance that opposes sepsis, putrefaction or decay; one that prevents or arrests the growth or action of microorganisms, either by inhibiting their activity or by destroying them; used especially of agents applied to living tissue.

*antiseptic, adj.* 1. Having the properties of an antiseptic; opposing sepsis, putrefaction or decay; preventing or arresting the growth or action of microorganisms, especially on or in living tissue. 2. Pertaining to, or characterized by, the use of antiseptics; as *antiseptic surgery*.

*Comments—*The word *antiseptic* is derived from two Greek words, *anti*, against, and *septikos*, putrefactive or rotting. The first known use of it in English, both as an adjective and as a noun, is (according to the *Oxford English Dictionary*) in the *Gentleman's Magazine* in 1751, where sea salt, myrrh and acids are spoken of as antiseptics. In 1774 Priestley remarked on the antiseptic power of "nitrous air" (nitrous oxide). At the time that the word came into existence it was not understood that putrefaction and decay are produced by the agency of microorganisms, but when this became known, the "preventing or arresting the growth or action of microorganisms" took its place naturally in the idea conveyed by the word. Apparently the earliest use of the term was with reference to substances to be applied as medicaments to sores and wounds, and the principal use even today is of substances applied to some part of the body, either externally or internally. The word *antiseptic* might be, and has been, applied to substances used to prevent decay in other connections, as of foods or timber, but such materials are usually called *preservatives* rather than antiseptics. It will be noticed that, as "antiseptic" is used, it may imply long-continued contact.

*Antiseptic and Germicide—*Since the killing of microorganisms is the most effective way to prevent their growth it would seem a logical conclusion that any germicide may act as an antiseptic. This appears to be the prevailing view. A great many writers who discuss the matter state or imply that an antiseptic may act either by inhibiting the growth of microorganisms or by killing them. A smaller

number, however, limit the action of an antiseptic to the prevention or arresting of bacterial growth *without* killing the organisms.

Now it is quite natural that, since we have other words such as *germicide* and *bactericide* to denote agents which actually kill microorganisms, the idea that an antiseptic may arrest growth without killing should be emphasized; but the majority of writers do not go so far as to contrast *antiseptic* with *germicide* and to regard the two terms as mutually exclusive. It seems best in accord with the history of the word and with prevailing usage to apply the term *antiseptic* to any agent which prevents further bacterial action, whether it does so by killing the bacteria or not. If this view be taken, any germicide might theoretically serve as an antiseptic. In practice there are exceptions. The action of certain non-material agencies, as sunlight and heat, is often referred to as germicidal but not as antiseptic. Again, many germicides cannot be used as antiseptics because of their harmful effect upon the body tissues. Bearing such exceptions in mind, however, we may say that in general a germicide is an antiseptic or has antiseptic properties.

On the other hand, it is not correct to say that an antiseptic is necessarily a germicide or has germicidal properties, for there are substances which are able to arrest the growth of microorganisms but are not germicides. Here again usage is not unanimous, for certain writers, chiefly those influenced by the practice of antiseptic surgery introduced by Lister, regard the action of antiseptics as a destroying one.

In an investigation of the relative number of authorities supporting each point of view, 165 definitions of *antiseptic* were studied, ranging in date from 1819 to 1930. Twenty, mostly early, make no reference to bacteria. Of the remainder, 66 state or imply that antiseptics arrest or destroy microorganisms, 27 state that they arrest but do not destroy, 12 that they destroy, and 10 that they inhibit growth (without stating how). Most of the remaining 30 definitions are not entirely clear, though a few represent divergent views, for example, that antiseptics neutralize toxins.

To illustrate recent usage on this point, 53 citations from works published in 1921 or later may be summarized as follows: (1) Describing an antiseptic as inhibiting or preventing the growth of microorganisms without necessarily killing them, 37. Of these, 12 are from bacteriological, 11 from medical, and 14 from miscellaneous sources. Three say definitely that antiseptics do not kill bacteria, and 4 more distinguish between antiseptic action as non-killing and disinfectant action as killing; the rest either say or imply that antiseptics may kill or else do not mention the question. (2) Stating that antiseptics destroy bacteria, 6. Of these, 2 are from surgeons, 1 is from a chemical dictionary which quotes alcohol and boric acid as examples, and 1 considers the "inhibiting" sense preferable. (3) Not giving a clear issue, or controversial, 10.

It should be remembered that whether a given substance is a germicide or an antiseptic, or neither, depends on several factors. One is the *strength* in which the agent is used; it may be a germicide in a solution of a certain concentration and only an inhibiting agent at a lower concentration. The *time of contact* and *mode of application* must also be taken into account; a solution which is germicidal when in contact with the material for 30 minutes may not be so for an exposure of 5 minutes, and imperfect contact of course lessens effectiveness. The *nature of the microorganism* must also be considered, since the resistance of different kinds varies greatly, so that a substance might be germicidal for one variety and only inhibitory

toward another, within a definite range of concentration. And there are still other factors, such as the *temperature*, the *abundance of the microorganisms* and the *nature of the material* in which the microorganisms are found.

#### DISINFECT, -TANT, -TION

##### *Definitions—*

*disinfectant, n.* An agent that frees from infection; usually, a chemical agent which destroys disease germs or other harmful microorganisms (but not, ordinarily, bacterial spores); commonly used of substances applied to inanimate objects.

*disinfectant, adj.* Freeing from infection, especially by destroying disease germs or other harmful microorganisms.

*disinfect, v.t.* To free from infection, especially by destroying disease germs or other harmful microorganisms.

*disinfection, n.* The act or process of disinfecting.

*Comments—*The verb *disinfect* first appears in the literature at about the beginning of the 17th century, and the other forms much later. Like *antiseptic*, this group of words came into use before the germ theory of disease originated. It was believed that certain "effluvia" existed in the air and on furniture, clothing, etc., and communicated certain diseases; hence, the infection must either be removed or destroyed. It is now recognized that the infection is caused by microorganisms, but we continue to use *disinfectant* as a convenient term for any agent that accomplishes the result of freeing from infection.

Wilcox (*Pharmacology and Therapeutics*, ed. 7, p. 13) states that "the term *disinfectant*, by extension, is applied to those agents which kill non-pathogenic bacteria, as well as to those which destroy disease germs." This, it seems, involves an extension of the meaning of the word "disinfection" to include freeing from other undesirable microorganisms besides those causing human disease.

*Disinfectant and Germicide—*For some time after the advent of the germ theory of disease, authors hesitated to describe the action of a disinfectant as being wholly or principally the destruction of microorganisms. They spoke of "restraining" or "neutralizing" the germs, of destroying the poisons produced, of deodorizing, etc. It would seem that their idea of "ridding of infection" was clear but not the precise method by which disinfectants operate. Popularly this vagueness persisted much longer. Albert Buck (*Reference Handbook of the Medical Sciences*, 1894) says: "Popularly, the term *disinfection* is used in a much broader sense. Any chemical agent which destroys or masks bad odors, or which arrests putrefactive decomposition, is spoken of as a *disinfectant* . . . This popular use of the term has led to much misapprehension." This misapprehension seems to have decreased with the spread of scientific knowledge.

Of 143 definitions of "disinfectants," dating from 1854 to 1930, 25 (chiefly of earlier dates) make no reference to microorganisms. Of the remainder, 95 define disinfectants as germ destroyers, 9 state that they may also act by removing the germs, and 8 say that they either destroy germs or arrest their action. Of the 95 citations, 52 define disinfectants as destroyers of *disease* germs, 34 merely say that they destroy germs or are germicides, while 9 specifically state that they destroy all germs, non-pathogenic as well as pathogenic.

Hence it seems to be generally expected that any substance used as a disinfectant will destroy the cause of infection, that is, will act as a germicide.

The word *disinfectant* still carries with it much of its original connotation. It suggests the cleaning of sick rooms, clothing, bedding, lavatories, stables and in

fact of any places or things that might harbor disease. By contrast, *germicide* is a precise, colorless word, conveying its literal meaning and little more. Aside from their history and connotations, however, *disinfectant* and *germicide* appear today to have the same meaning when applied to substances used in fighting disease.

*Disinfectant and Antiseptic*—If we accept certain conclusions from the above discussion, namely, that the substances called disinfectants are germicides, and also that in general germicides may act as antiseptics but that antiseptics are not necessarily germicides, then it follows that disinfectants may (theoretically at least) act as antiseptics, but that antiseptics may not necessarily act as disinfectants. Due attention should of course be paid to the different connections in which the two words are used.

#### STERILIZE, -ZATION

##### *Definitions—*

*sterilize, v.t.* To render sterile, that is, free from all living microorganisms.

*sterilization, n.* The act or process of sterilizing, or freeing from all living microorganisms.

*Comments*—These are exact terms, which came into use (in the sense under discussion) to express a precise idea, namely the freeing of a material, container, or space from living microorganisms of all kinds. There is no distinction between disease germs and other germs, or between resistant and nonresistant varieties or forms. If a thing has been treated in such a way that no growths can be produced from it by appropriate culture, then—and then only—has it been completely *sterilized*.

One of the best ways to accomplish sterilization is maintaining for a sufficient time at a temperature at which microorganisms cannot live; hence the use of the word *sterilize* suggests to some the destruction of microorganisms by *heating*. To others it includes also the notion of the use of strong chemical agents. The word calls to mind the treatment of surgeons' instruments, gauze bandages, culture dishes, and other apparatus rather than the treatment of the sick room or of the human body.

*Disinfect and Sterilize*—It has been noted that *disinfect* refers particularly to the destruction of disease germs (especially the vegetative forms), while *sterilize* denotes the freeing from all organic life. Hence *sterilize* is the more drastic of the two terms and it might easily happen that something is thoroughly disinfected without being completely sterilized. This is true, for example, of the customary treatment of milk cans, milk bottles, etc., in the dairy industry, where treatment sufficient to prevent diseases and spoiling of the milk is not necessarily sterilization.

#### DEODORANT, -RIZER

##### *Definition—*

*deodorant, deodorizer, n.* Anything that destroys or masks offensive odors.

*Comments*—A deodorant may or may not be an antiseptic or disinfectant. The popular notion that danger from infection disappears with the removal of disagreeable odor is of course a mistaken one.

#### INSECTICIDE, -DAL

##### *Definitions—*

*insecticide, n.* A substance that destroys insects, especially a preparation used for this purpose.

*insecticidal, adj.* Of or pertaining to insecticides; destroying insects.

*Comments*—As defined, the word *insecticide* is limited to the destruction of in-

sects. The Insecticide Act of 1910 defines it somewhat more broadly, however, as "any substance or mixture of substances intended to be used for preventing, destroying, repelling, or mitigating any insects." Also, the Food and Drug Administration admits within the term *insect* small invertebrate animals such as spiders and mites which do not belong to the order Insecta but are liable to be called insects in popular language. Insecticides may be effective against one type of insect but not necessarily against all types of insects. Insecticides usually act as stomachic or respiratory poisons; their method of application or use varies with the type of the insecticide and of the insect against which it is applied. An insecticide although usually used to destroy insects does not necessarily give a 100 per cent kill.

#### DISINFEST

##### *Definition—*

*disinfest, v.t.* To rid of infestation; to free from infesting insects, rodents or other small animals.

*Comments—*The earliest appearance of the word of which the committee has record is in the report of the Committee on Standard Regulations for the Control of Communicable Diseases, A. P. H. A., 1926, in which the following definition appears: "By disinfecting is meant any process, such as the use of dry or moist heat, gaseous agents, poisoned food, trapping, etc., by which insects and animals known to be capable of conveying or transmitting infection may be destroyed."

Since a word covering the above process was apparently needed, and since the inclusion of this sense in the meaning of *disinfect* (as has been the practice of some) seems incorrect and undesirable, the introduction and use of the comparatively new word *disinfest* are to be commended.

#### PROPHYLACTIC

##### *Definitions—*

*prophylactic, n.* Anything that prevents, or that contributes to the prevention of, disease; a preventive.

*prophylactic, adj.* Guarding from disease; preventing, or contributing to the prevention of, disease.

*Comments—*The meaning of *prophylactic* is wide. It applies to anything which even helps to ward off disease, as fresh air, nutritious diet, and rest, which serve as preventives of tuberculosis and other ailments. One writer has even used the term "mental prophylactics." Various medicinal preparations are also called prophylactics. It would seem however that a substance, to be called a prophylactic against a given disease, should be demonstrated to have some efficacy for the purpose in question under the conditions of its intended use.

#### CONCLUSION

It has been announced as a principle of legal practice that "language used in the label is to be given the meaning ordinarily conveyed by it to those to whom it is addressed." This commends itself as a sound and wise ruling, for the general public cannot be expected to be acquainted with special technical meanings or to have information proper to experts alone. Nevertheless, it is possible to draw wrong conclusions from this principle. People constantly make use of words of which they do not know the accurate meaning. They know barely

enough about it for ordinary purposes; the rest they leave to the specialist. This is eminently true of such things as drugs and medicaments. It is small wonder that similar terms are sometimes confused in the popular mind:

It may of course happen in the development of language that a term becomes so confused that it undergoes a complete change of meaning and that the new meaning becomes commonly accepted. But the mere fact that the average person has a confused notion of a word which is used correctly by writers and careful speakers does not justify acceptance of the confused meaning.

The terms *antiseptic* and *disinfectant* may be taken as examples. There appears to be some haziness in the mind of the public regarding their signification; yet the greater part of the literature is in fair agreement as to the derivation, history, and present meaning of the two words. Moreover, what popular confusion may exist is not so much with respect to the *root idea* of the words ("antiseptic," opposing decomposition; "disinfectant," ridding of infection) as regarding the mechanism by which the result is effected (removing germs, killing germs, or preventing the growth of germs). It is the result that chiefly concerns the public; the expert must be relied on for exact knowledge of the mechanism.

So far as the writer can determine after talking with various persons, bacteriologists, physicians, druggists, manufacturers of chemicals, and government officials, there do not seem to be serious differences of opinion among professional men as to the meanings of the various terms now under discussion.

In so far as differences exist, they seem to relate rather to the question as to what is a fair use of the terms in connection with certain manufactured products, when the circumstances under which these products are to be used are duly considered. For example, there seems to be pretty general agreement that the term *antiseptic* (at least aside from surgery) may properly be applied to a substance which merely arrests the growth of microorganisms without killing them. There is apparently no question, for example, as to advertising a bandage impregnated with iodoform as an antiseptic dressing for wounds or as to calling iodoform or any similar agent an antiseptic when so used. The question seems to be whether a substance which is not a germicide but which acts as an antiseptic so long as it remains in contact with the area to be protected can fairly be called an antiseptic when its application is necessarily brief as in the case of a mouth wash, gargle or tooth paste. Again, the agreement on the meaning of the term *prophylactic* seems to be good. It is recognized as a very broad term.

Apparently the main question at issue, if there is one, is under what circumstances a given substance may fairly be claimed to have a prophylactic effect.

The adjustment of such questions as to what is fair under different circumstances seems to lie outside the province of defining meanings of words. It seems to be a matter of bacteriological and medical knowledge, a spirit of fair play, and good common sense. If the writer may hazard a suggestion, it would be that, since the correct application of certain terms of which *antiseptic* and *disinfectant* may serve as types depends on a number of factors (in the present case, strength, time of contact, type of organism, etc.), due regard should always be had to these factors as they occur, or are likely to occur, in actual practice.

---

## Honor to Whom Honor Is Due

THE address of Stokes<sup>1</sup> has elicited an answer and brought out references which have been overlooked or forgotten by the majority of people of this age. The particular statement involved is that "Metchnikoff with Roux 'had accomplished the first successful transfer of syphilis to apes' in 1905." From these reports and the discussion<sup>2</sup> given of them, it seems certain that Edwin Klebs, whose name combined with that of Loeffler is so well known in connection with the discovery of the germ of diphtheria, had seen the spirocheta in the lesions of syphilis nearly 30 years before the discovery by Schaudinn, and had inoculated apes with the material, with the production of characteristic lesions.

The report by Klebs states "(1) that in syphilitic lesions there are regularly found spirillar organisms, slender motile rods 2 to 5 microns long, which seem to belong in Ehrenberg's botanical group of monads, and which Klebs names, because of their spirillar shape, 'helico-monads'; (2) cultures of these organisms are obtained on a special medium of isinglass jelly; (3) successful transfer of syphilis to animals was obtained only in apes (*Macacus*), very suggestive but not entirely conclusive results in the case of subcutaneous inoculation of culture material (July 8, 1875), entirely conclusive in the case of inoculation with freshly excised material from a human primary lesion (December 29, 1877)."

Dr. Klebs, a son of Edwin Klebs, recognizes that there is now no way to control the exactness of the findings reported, but states that Metchnikoff recognized that Klebs was the first to have seen the spirocheta and to have inoculated apes with syphilis. Further, Ghon made the statement that at the Pathological Institute at Prague the skull of the second ape inoculated was still preserved and showed characteristic lesions.—Arnold C. Klebs, *Discovery and Discoverers*, *Science*, Feb. 12, 1932, p. 191.

# A Health Aspect of Frozen Vegetables\*

R. P. STRAKA AND LAWRENCE H. JAMES

*Food Research Division, Bureau of Chemistry and Soils, U. S. Department of Agriculture, Washington, D. C.*

THE commercial preservation of foods by freezing storage apparently began at Salem, Ore., about 20 years ago, when berries were first frozen in large containers for hotel and wholesale trade. Later, freezing was widely used for the preservation of fish. Large quantities of fish are now frozen and marketed in retail containers, facilitating handling and improving considerably the sanitary conditions.

In recent years the number of different foods preserved and marketed in a frozen condition has tremendously increased. At present, many fruits and some vegetables are being stored in this manner. Numerous difficulties have arisen in developing methods best suited to the freezing of these and similar products, and some are still unsolved. In the marketing and handling of frozen fruits and vegetables, one question is of paramount importance, not only from the standpoint of public health, but the future of the entire frozen-food industry. The possibility of botulinus poisoning resulting from the consumption of defrosted, improperly handled vegetables and fruits must be considered. Marketing such products through the small grocery store directly to the consumer increases considerably the importance of this factor.

As the preservation of foods by freezing is comparatively new, it has received very little attention from bacteriologists or public health workers. Because of the lack of information on the occurrence and importance of botulinus spores on frozen vegetables, an extensive investigation was undertaken to determine the survival of these microorganisms in such products and their possible production of toxin when the vegetables have been improperly handled after defrosting or when they are accidentally defrosted during storage or transportation.

As far as we are aware, the commercial freezing of vegetables has been confined to limited amounts of peas, spinach, and asparagus. Green peas, however, have been widely considered for preservation by this method. Moreover, of the vegetables commercially frozen, peas are believed to be the most susceptible to microbial decomposition, and

---

\* Read before the Food, Drugs and Nutrition Section of the American Public Health Association at the Sixtieth Annual Meeting at Montreal, Canada, September 14, 1931.

they are known to support abundant growth of, and toxin production by *Clostridium botulinum*. For these reasons peas were selected for this investigation.

The investigation was divided into two parts: a study of the effect of freezing on *Cl. botulinum* spores, both as regards survival and toxicity, and the possibility of the development of botulinus toxin in peas which had been improperly handled after defrosting or when accidentally defrosted during storage or transportation. Neither study has been completed, but the latter is reported in part here.

#### CONDITIONS STUDIED

The samples were all packed, inoculated, and frozen in Seattle, Wash., which might be considered the center of the industry at present. The investigation included:

1. Three methods of preparing the peas: (all hand shelled)
  - a. Washed in cold water
  - b. Washed in cold water, then blanched in boiling water
  - c. Washed in cold water, then blanched in boiling brine
2. Four types of containers:
  - a. No. 2 plain tin cans (sanitary type)
  - b. Rectangular 1-lb. cardboard boxes (known as "Peters" containers)
  - c. Wide-mouthed 16-oz. commercial glass jars equipped with metal friction caps for sealing under a vacuum
  - d. 1-lb. cardboard monotubs (circular cardboard "tubs" with cardboard tops)
3. Three degrees of inoculation with *Cl. botulinum* spores:
  - a. No inoculation (controls)
  - b. Dilute inoculation (see text)
  - c. Concentrated inoculation (see text)
4. Two methods of packing:
  - a. With vacuum (tin and glass containers only)
  - b. Without vacuum
5. Four methods of defrosting:
  - a. Water bath at 43° C. and examined immediately
  - b. Icebox for 3½ days (½ day for defrosting, then 3 days storage)
  - c. Room temperature for 3½ days
  - d. Water bath at 43° C. until defrosted (2 hours), cooked in 2.5 per cent brine on open fire, then stored at room temperature for 3 days

Each test condition was selected because of some particular relationship it bears either to the handling of frozen peas or to the growth of *Cl. botulinum*. The four types of containers have all been recommended for commercial use in freezing vegetables. Further, the con-

ditions of anaerobiosis might be different in the various types of containers. Three methods of treating peas prior to packing have been recommended. The natural resistance of plant tissues to bacterial invasion is retained for some time after the product has been removed from the plant, but it is largely destroyed by hot water. Blanching, therefore, might exert considerable influence in the growth of botulinus in the defrosted peas. Blanching in hot brine was used to determine the inhibitive action of salt on these microorganisms.

The influence of large numbers of bacterial spores on the sterilization of food products has been well shown by Bigelow and Esty<sup>1</sup> and their coworkers in studies of the factors which influence thermal-death-time determinations. Whether or not a similar influence would occur in the freezing of large numbers of spores was not known; therefore, each series was prepared in triplicate. The first, not inoculated, served as controls; in the second each filled container was inoculated with less than 100 botulinus spores; and in the third with approximately 100,000,000 spores. The technic of inoculation is outlined later.

The importance of a vacuum in the possible growth of botulinus spores in such a product hardly needs explanation. Since *Cl. botulinum* is an anaerobe, the removal of air may materially aid growth. The vacuum packing was confined to the tin and glass containers.

The various methods of defrosting were planned to duplicate as far as possible conditions which might occur in the marketing and consumer handling of the product. Examination immediately after defrosting shows whether or not toxin has been formed while the product was frozen or was released from the spores by mechanical injury in freezing, and also serves as a control on the other treatments. Holding in the icebox for  $3\frac{1}{2}$  days may occur in the home. Approximately  $\frac{1}{2}$  day is required to defrost the product in a small ice refrigerator. Storage at room temperature for  $3\frac{1}{2}$  days allows something less than  $\frac{1}{2}$  day for defrosting and a storage period of about 3 days. The fourth method of treatment consisted in defrosting in a  $43^{\circ}$  C. water bath, boiling the peas in a 2.5 per cent brine for 10 minutes, then storing them in pint jars at room temperature for 3 days in order to determine the effect of cooking on the susceptibility of peas to the development of botulinus toxin.

Each test series of containers was assigned a number for later reference, which, with the conditions under investigation in each series, are given in Table I.

Under each test condition at least 16 containers were prepared. More than 1,000 containers were used, including 320 for tests on the influence of the length of storage in a frozen condition on the numbers

TABLE I  
SERIES NUMBERS USED IN PREPARATION OF THE SAMPLES

Conditions Tested		Inoculation	Types of Containers *			
			Mono-tubs	Peter's Type	Tin Cans	Glass Jars
Blanching	Washed cold water	None	1	10	19	28
		Dilute	2	11	20	29
		Concentrated	3	12	21	30
	Washed cold water, blanched hot water	None	4	13	22	31
		Dilute	5	14	23	32
		Concentrated	6	15	24	33
	Washed cold water, blanched hot brine	None	7	16	25	34
		Dilute	8	17	26	35
		Concentrated	9	18	27	36
Vacuum	With vacuum †	None			37	43
		Dilute			38	44
		Concentrated			39	45
	No vacuum †	None			40	46

† Peas washed in cold water and blanched in hot water

of *Cl. botulinum* spores living. This latter section of the investigation has not been completed and will not be reported here.

TECHNIC OF INOCULATION AND PACKING

One of the greatest difficulties encountered in extensive investigations with the botulinus microorganisms is the possible variation in toxicity when the organisms are subcultured in mediums over extended periods of time. This was overcome by the preparation of sufficient dried spores to make all inoculations. As vegetables generally carry some soil contamination, they are usually washed in water and blanched before they are packed for freezing. In the soil, botulinus spores are in a more or less dry state, but if present on the peas, they become moistened during washing or blanching, and if they remain are probably frozen while wet. To duplicate these conditions as closely as possible, buffer suspensions of dried *Cl. botulinum* spores were used in the inoculations. The dried spores were prepared according to the following technic: \*

\* The dried spores were prepared by Elizabeth W. Sommer at the William Hooper Foundation for Medical Research in San Francisco, Calif.

1. Cultures were grown on casein-digest agar (pH 7.4) for 5-6 days at 37° C.
2. The growth was suspended in distilled water, centrifuged, and washed twice with distilled water, twice with alcohol and twice with ether.
3. The material was then dried *in vacuo*.
4. The total number of living spores and their heat resistance were determined.

Because cultural differences are important in investigations involving the botulinus microorganism, the following 4 strains were used in this study:

1. *Clostridium botulinum*, Type A, strain No. 19, isolated from asparagus which was held responsible for the botulism outbreak at Boise, Ida.
2. *Clostridium botulinum*, Type A, strain No. 62, isolated from a liver infarct of a cow at Redwater, Nev.
3. *Clostridium botulinum*, Type B, strain No. 174, isolated from Italian canned onions.
4. *Clostridium botulinum*, Type B, strain No. 186, isolated from canned ham.

A mixture containing equal amounts of dried spores of each of these strains was prepared, and for inoculation definite quantities weighed on an analytical balance were suspended in Sorenson's buffer solution of pH 6.9 (2) and suspended by shaking with glass beads. It was found desirable to add 2.0 c.c. of the suspension to each container. Each 2.0 c.c. was made to contain 1.0 mg. of dried spores, so that with the most concentrated inoculations, each container received approximately 100,000,000 spores.

The inoculations were made in Seattle, Wash., and all samples opened and examined in Washington, D. C. In preparing the suspensions the work was done in one room, and the raw materials, samples, and inoculations were handled in a distant room. All equipment and suspensions were either sterilized or soaked with a solution of mercuric chloride after each day's run. No materials except the stock supplies of dried spores were carried over from one day to the next.

The peas, shelled by hand, were purchased from a Japanese grower in the vicinity of Seattle who delivered the desired quantity to the laboratory daily. What influence this method of shelling had on the spore contamination is not known.

#### PROCEDURE

About 5 lb. of peas were placed in a covered wire basket and agitated vigorously in a tank of clean, cold water. By this procedure, a large part of the dirt was removed. After they had drained about 2 minutes, some were packed in the containers, and the rest blanched by immersing in boiling water. The cold peas lowered the temperature of the water about 10° C. The water resumed boiling in about

FIGURE I

APPARATUS USED IN SEALING TIN CONTAINERS UNDER A VACUUM

2 minutes and the peas were removed approximately 2 minutes later. After blanching, they were cooled and the containers filled.

The filled containers were inoculated immediately with 2.0 c.c. of the spore suspensions. Preliminary tests with eosin solution had shown that this amount of added liquid would give a reasonably uniform inoculation. The monotubs were closed by pressing into place the waxed cardboard tops. The "Peters" type boxes were closed, wrapped in moisture proof wax paper and tied with cord. In commercial practice the wax wrapper is generally sealed in place in order to make the container as moisture proof as possible. The tin cans were sealed on a hand sealing machine.\*

The containers which were to be packed under a vacuum were punctured through the lid with a small nail, then placed in a desiccator, through the top of which an electric soldering iron had been fitted by means of rubber tubing or a flexible cork stopper (Figure I).

A small piece of solder containing flux was placed beside the opening in the can lid, and the desiccator was closed. When a vacuum of 20 inches had been drawn, the hot iron was used to seal the hole, the vacuum released, and the can removed.

\* The authors are indebted to the Research Laboratories of the Continental Can Company for the method of sealing individual tin containers under a vacuum.

The glass jars were sealed by means of a vacuum sealing machine,\* although the vacuum was used in only a part of the containers.

After the containers had been closed they were put in storage as rapidly as possible, but as the cold storage was located at some distance, 5 hours elapsed before some reached the freezing room. They were placed on the floor of a storage room maintained at 10° F. and widely separated so as to allow as rapid freezing as possible. Each was frozen within a few hours. They were left in the freezing room until shipped.

Preparation and freezing of all the samples required 25 days. The period of storage in Seattle ranged from 7 to 25 days. Studies to be reported later have shown not only that the period of freezing storage does not influence the number of spores surviving, but also that different rates of freezing ("quick-freezing" or "slow-freezing") do not have different effects upon the spore population.

When all the samples had been frozen, they were packed in fiber cases, insulated with shredded paper, and sealed, then loaded into a pre-cooled refrigerator car, and packed on the floor immediately in front of the lower opening in the ice bunker. At Chicago, all samples were removed to a freezing storage room (0° F.) and held there for 24 hours. Although the samples were in good condition and possibly did not need additional freezing, the procedure was adopted as a precaution against defrosting. The cases were then packed into the end of a pre-cooled refrigerator car and shipped to Washington, D. C., where they were transferred immediately to a cold room, and stored at a temperature of approximately 18° F. until removed for examination.

#### EXAMINATION OF SAMPLES

The samples were defrosted according to 4 procedures. In defrosting those for immediate examination the tin containers, after removal from cold storage, were immersed at once in a water bath maintained at 43° C. The cardboard containers were placed in a pan which was lowered into the water, and the entire bath was covered. They required a slightly longer period for complete defrosting than did the tin containers.

Another series of containers was defrosted in an icebox and stored there for 3 days. The icebox was small and poorly insulated. The temperature of the food compartment varied somewhat, although the box was iced daily. At the end of the storage period the samples were examined as later described.

The containers defrosted at room temperature were left undisturbed on the laboratory table for 3½ days, during which most of the

---

\* Loaned by the Hazel-Atlas Glass Company.

tin containers swelled so much that puncturing was required, a very small hole being made in each lid. After  $3\frac{1}{2}$  days the samples were examined according to a regular laboratory procedure.

The peas which were to be cooked were defrosted in the  $43^{\circ}$  C. water bath; transferred to an open pan; 500 c.c. of 2.5 per cent salt solution was added; and the whole was boiled vigorously for 10 minutes. In this time practically all the liquor boiled away. This was made up to original volume; the peas and liquor were transferred to a sterile pint jar and allowed to cool. The lid was then loosely clamped on, and the jar stored at room temperature for 3 days. At the end of this time the examination was made as outlined below.

The samples for immediate examination were completely defrosted, and at the end of the storage period for those left at room temperature and in the icebox, the peas of each sample were transferred to a sterile pint jar. The original containers were washed out with 50 c.c. of sterile water, which was added to the pint jar. During most of this study the peas were then crushed with a sterile spoon. Each jar was shaken vigorously 50 times. The liquor was then removed and divided into several parts as indicated in Figure II. One portion was used for the determination of total anaerobic bacterial and spore counts and the isolation of *Cl. botulinum*, one for the determination of the pH, and one for toxicity tests. Another portion, together with each pint jar and its contents, was held in reserve in cold storage.\*

Total numbers of anaerobic bacteria as well as spores were determined on each sample by the dilution method. Beef-heart medium, sterilized by heating 3 times in flowing steam, with incubation periods between, was used. All tubes were tested before use by incubation for 5 to 7 days at  $37^{\circ}$  C., and rarely were non-sterile tubes found.

In making the spore counts, tubes of the liquor removed from the peas were first heated in boiling water for 10 minutes. After inoculation, the tubes of medium were stratified with autoclaved vaseline, and incubated for at least 3 weeks at  $37^{\circ}$  C. All series of tubes were run in duplicate. Two sets of results have been noted, (1) the greatest dilution at which gas was produced in the beef-heart medium; (2) the greatest dilution which showed growth resembling that produced by *Cl. botulinum*.

In studying samples which did not contain botulinus toxin an effort was made to identify *Cl. botulinum* in the anaerobic tubes prepared for spore determination. For this purpose the tubes representing the greatest dilution showing growth resembling that of *Cl. botulinum* were

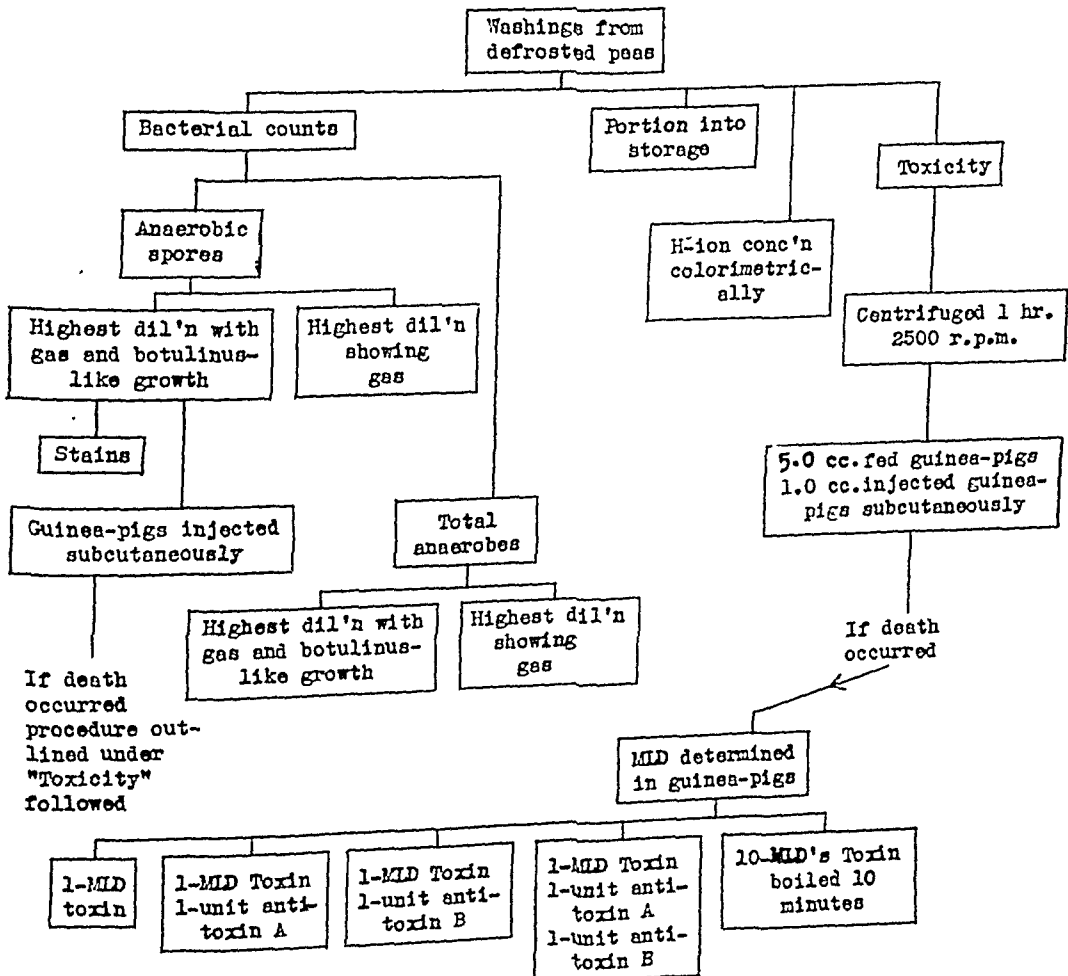

\* In the first part of the investigation the reserve portions of the samples were stored at  $34^{\circ}$  to  $36^{\circ}$  F., but later these and all subsequent portions were stored at  $18^{\circ}$  to  $20^{\circ}$  F.

used. The suspected cultures were injected subcutaneously into guinea pigs, and the culture was identified by neutralization of the toxin with antitoxin, according to standard procedures.

The pH of the various samples was determined colorimetrically, occasionally checked electrometrically.

Toxicity tests were made on the liquor removed from every container. The wash water was centrifuged at approximately 2,500 r.p.m. for 1 hour, which yielded a clear liquor satisfactory for feeding and injection. Guinea pigs have been used since preliminary comparisons of their reactivity with that of white mice indicated that much greater reliability could be placed upon the results with the former in this particular investigation. The centrifuged liquor of each sample was administered to 4 guinea pigs. Two were force fed, and 2 were injected subcutaneously. The fed pigs each received 5 c.c. per 250

FIGURE II  
LABORATORY EXAMINATION OF SAMPLES

gm. of body weight, the injected ones 1 c.c. per 250 gm. Proportionate dosages were used for pigs varying from the standard weight, but in no case was an animal used for forced feeding that required more than 5 c.c.

When the pigs showed no reaction the sample was rated negative for the presence of toxin. If illness or death occurred in at least 1 pig, further tests were made to determine whether or not it was caused by botulinus toxin, and if so to identify the type of culture responsible.

The centrifuged liquor and physiological salt dilutions thereof were injected subcutaneously into guinea pigs, 1 c.c. per 250 gm. of body weight. The smallest amount, that is, the highest dilution, causing death within 96 hours, was the m.l.d. for that particular sample. A final confirmatory series was run as follows:

1. One m.l.d. toxin
2. One m.l.d. toxin and 1 unit of antitoxin, Type A
3. One m.l.d. toxin and 1 unit of antitoxin, Type B
4. One m.l.d. toxin and 1 unit of antitoxin, Type A,  
and 1 unit of antitoxin, Type B
5. Ten m.l.d.'s toxin heated in boiling water for 10 minutes

Two pigs were used for each of these combinations. Sterile physiological salt solution was used as a dilution medium. The mixtures were adjusted so that 1 c.c. contained the proper dosage for 250 gm. of body weight. The toxin-antitoxin combinations were carefully mixed, and allowed to stand at room temperature for 1 hour before injection subcutaneously into guinea pigs. The findings are reported only when definite results were obtained within 96 hours. In no case were they considered positive until clear-cut results were obtained, and the identity of the toxin was proved.

## RESULTS

Before discussing the results in detail it should be emphasized that toxin was obtained only in the defrosted samples of peas that had been held at room temperature, and that all of these were definitely spoiled. No toxin was obtained from containers defrosted and examined immediately or from containers defrosted and held in an ordinary icebox.

The examinations of only the tin and the cardboard containers have been completed. The former were finished before the latter were studied.

## TIN CONTAINERS

Seventy-two tin containers of frozen peas were examined; 24 had received no inoculation, 24 the dilute inoculum, and 24 the concentrated. Each of these lots was subdivided so that samples were de-

frosted according to each of the 4 methods described. During storage 14 of the containers became toxic, including 2 controls, 4 that had received dilute inoculation, and 8 that had received heavy inoculation, and 8 of the uninoculated containers yielded *Cl. botulinum* cultures. The results are summarized in Table II.

TABLE II  
BOTULINUS TOXIN AND CULTURES FOUND IN PEAS IN TIN CONTAINERS

Total Containers	Inoculation	Tins Containing Botulinus Toxin			Tins Containing Botulinus Spores

24	Dilute	4	16.6	2 Type A 2 " B	12 *	50.0 *
24	Concentrated	8	33.3	2 Type A 6 " B	24 *	100.0 *
Total 72		Total 14	19.4	Total 4 Type A 10 " B	Total 46 *	63.8 *

\* Presumptive.

The cultures isolated from the containers receiving the dilute and concentrated inocula have not been identified or typed, since such information would add little to the results obtained. The isolation of *Cl. botulinum* spores (presumptive) from only a few more of the dilute-inoculated containers than from the uninoculated controls indicated that the "dilute" inoculum contained only a few botulinus spores per c.c. Dilution counts in beef medium had shown approximately 10 spores per c.c. of suspension.

The results when the various toxic containers are considered from the standpoint of the different methods of defrosting and storage are very interesting. The 72 containers referred to in Table II are classified in Table III according to their treatment following defrosting.

In Table III a striking contrast is revealed between the containers of peas defrosted and held under varying conditions. Particularly striking were the results on the peas which, after being boiled for 10 minutes, developed toxin at room temperature.

The tests for total anaerobic bacteria and total anaerobic spores showed that in almost all containers the total anaerobic cells far outnumbered the spores. The length of the period of holding at

TABLE III

NUMBER OF TOXIC TIN CONTAINERS OBTAINED UNDER EACH OF 4 METHODS OF DEFROSTING AND STORAGE

Total containers	Inoculation	Containers Defrosted by			
		Water bath at 110° F. Not held	Icebox held 3½ days	Room temperature held 3½ days	Water bath at 110° F. Brine cooked held Room temperature 3 days
24	None	0	0	0	2 (8.3%)
24	Dilute	0	0	0	4 (16.6%)
24	Concentrated	0	0	2 (8.3%)	6 (25%)
Totals 72		0	0	2 (2.7%)	12 (16.6%)

temperatures after defrosting, of course, influenced these counts. Table IV shows the results obtained on the uninoculated tin containers. The studies so far have not covered those blanched in brine. Duplicate containers for each test condition have been examined. The "Sample Numbers" are as given in Table I. Each container number has received a letter in accordance with the method of defrosting and storage, as follows:

- 1. Water bath ..... A and B
- 2. Icebox—3½ days ..... C and D
- 3. Room temperature—3½ days ..... E and F
- 4. Water bath—boiled—held room temperature .... G and H

The nature of the botulinus cultures isolated from the uninoculated tin containers is of interest to both the food technologist and bacteriologist. The survey of various soils made by Dubovsky and Meyer showed that botulinus spores are present in a large number of gardens. The isolation of botulinus spores then from a comparatively large number of the uninoculated containers is of exceptional interest. The relation of the methods of preparation and defrosting to the type of botulinus culture obtained is given in Table V. Of the 24 uninoculated containers examined, cultures were isolated from 6 in which the peas had not been blanched and had not become toxic, and 4 were from peas which had been blanched, 2 of which contained toxin. This is

particularly interesting in view of the fact that in most of the containers which showed *toxin* the peas had been blanched.

It is also significant that half the cultures isolated from the uninoculated peas were Type A, and half (including those demonstrated by toxin production) Type B, while, as given in Table II, of the 14 containers showing toxin, 4 were Type A and 10 Type B.

A correlation can be seen between the types and strengths of the toxins and the methods of preparation and defrosting. Table VI shows such a correlation, including the findings with the inoculated materials. The predominance of Type B is striking.

CARDBOARD CONTAINERS

Results with peas packed in cardboard containers were interesting. There were only 48 of these, as none of this series was packed under a vacuum. The methods of preparation were exactly the same as used with the tin containers. Twelve per cent of the uninoculated cardboard containers became toxic. As in the tin containers, practically

cardboard containers) which had received no artificial inoculation, *Cl. botulinum* cultures were isolated from, or demonstrated in, 15, or 37.5 per cent.

Four methods of defrosting were used, the same as with the tin containers. No toxin was produced when the containers were defrosted and examined immediately, or when they were defrosted in the icebox and stored there for 3 days. This was true even when the peas had received a heavy inoculation of botulinus spores. When the peas were defrosted at room temperature, and allowed to stand for 3 days, toxins developed in 2 out of 4 uninoculated containers, and in 7 of the 12 tested by this method. Of the 12 which were first cooked in brine and then stored at room temperature, only 2 became toxic. These 2 had received the concentrated inoculum. The results are summarized in Table VIII.

TABLE VIII

NUMBER OF TOXIC CARDBOARD CONTAINERS OBTAINED UNDER EACH OF 4 METHODS OF DEFROSTING AND STORAGE

Total containers	Inoculation	Containers Defrosted by

16	Concentrated	0	0	3 (18.7 %)	2 (12.5 %)
Totals 48		0	0	7 (14.5 %)	2 (4.1 %)

Determinations of the number of anaerobic bacteria as well as anaerobic spores were also made on all the cardboard containers. The results, together with the pH, method of defrosting, and demonstration of the botulinus organisms, are given in Table IX. As indicated, wherever possible the isolation of botulinus microorganisms was made from the tubes prepared for the determination of the numbers of spores. In this series of uninoculated containers, however, no botulinus-like growth was observed in the spore tubes. Therefore trans-

fers were made from the other series of tubes (those for the total anaerobic counts) wherever such was indicated by the proper growth. Five isolations of *Cl. botulinum* were made, 3 Type A, and 2 Type B.

TABLE IX

\* Demonstrated in anaerobic count tubes, not spore count.

The connection between the types of botulinus cultures isolated and the methods of preparation and defrosting (Table X) is analogous to that noted in the tin container series, namely, that both A and B types occurred with about equal frequency, apparently independent of the method of defrosting and storage, but closely associated with blanching. The majority of Type A cultures were obtained from lots

which had only been washed in cold water, whereas most of the Type B were isolated from lots which had been washed in cold water and then blanched in hot water.

TABLE X

13F	" " "	" "	B	10

\* These cultures were obtained from tubes of anaerobic count series, not from spore count series.

The data on the types and strengths of toxins in the cardboard containers (including the inoculated and the uninoculated) reveal further interesting information. Nine of the 48 containers showed toxin, 6 Type B, and 3 Type A. All the Type B toxins were produced in peas which had been blanched. These results are shown in Table XI.

\* See 5c under "Conditions Studied."

One interesting difference appears between the 2 types of containers. Leaving out of consideration the peas packed under a vacuum, we find that the toxins developed in the cardboard boxes were a little less potent than those in the tin containers.

#### SUMMARY

1. Twelve hundred containers of peas were prepared and frozen in Seattle, Wash., shipped to Washington, D. C., for study. The investigation included 4 types of containers, 3 methods of preparation, 3 degrees of inoculation, 2 methods of packing, and 4 methods of defrosting.

2. The peas, before freezing, were inoculated with buffer suspensions of dried *Cl. botulinum* spores. A mixture of 4 strains of *Cl. botulinum* (2 Type A and 2 Type B) was used.

3. All the peas were frozen in a cold storage room at 10° F.

4. The following determinations were made on each container:

- a. Total anaerobic bacteria
- b. Total anaerobic bacterial spores
- c. Botulinus cultures isolated where possible from the uninoculated peas
- d. H-ion concentration
- e. Toxicity—Botulinus toxins, when present, identified in guinea pigs

5. Examination of 24 tin containers of uninoculated peas, most of which were held for 3 days after defrosting, showed 2 to be toxic. Eight others yielded botulinus cultures, 2 of which were obtained from samples examined immediately after being defrosted.

6. Examination of 24 tin containers of peas lightly inoculated, most of which were held for 3 days after defrosting, revealed that 4 were toxic.

7. Of 24 tin containers which had received a heavy inoculation, most of which had been held for 3 days after defrosting, 8 were toxic.

8. Of 16 cardboard containers which had received no inoculation and most of which had been held for 3 days after defrosting, 2 were toxic, and 3 others yielded botulinus cultures.

9. Of 16 cardboard containers which had received a light inoculation and most of which were held for 3 days after defrosting, 2 were toxic.

10. Of 16 cardboard containers which had received a heavy inoculation and most of which had been held for 3 days after defrosting, 5 contained toxin.

11. No toxin developed in peas which were examined immediately after defrosting, and none developed in those defrosted and held for 3 days in the icebox.

12. The contents of all the containers which showed toxin had been stored at room temperature and were badly spoiled when examined.

13. From the uninoculated peas (both types of containers) both Type A and Type B cultures of *Cl. botulinum* were isolated in approximately equal numbers, 8 Type A and 7 Type B.

14. Of the peas that were blanched and later became toxic (both types of containers), 3 showed Type A toxin whereas 14 showed Type B. Of the peas that became toxic after having been washed in cold water without blanching (both types of containers) 4 showed Type A toxin, and 2 Type B.

In the total of 23 toxic containers, 7 were Type A, and 16 Type B.

15. Of the total of 4 uninoculated samples which showed toxin, 2 were ob-

tained from the tin and 2 from the cardboard containers, and in both kinds of containers the peas had been blanched. The toxin in all 4 was Type B.

#### ACKNOWLEDGMENTS

In planning this investigation and throughout the course of the work the authors have called freely upon the advice of others and gladly acknowledge their valuable assistance. Particular credit is due to Dr. K. F. Meyer, Dr. J. R. Esty, and Dr. F. C. Blanck for their advice and criticisms. The authors are very grateful to Elizabeth W. Sommer, at the William Hooper Foundation for Medical Research, San Francisco, for the preparation of the dried botulinus spores used in this study. The investigation was aided considerably by the donation of various containers by the Continental Can Company, Hazel-Atlas Glass Company, and General Foods, Inc., and by other assistance. Laboratory facilities for the preparation of the samples were provided by the Seattle Laboratory of the Food and Drug Administration. The samples were frozen and stored in Seattle by the Port of Seattle, the municipal dock refrigeration house, whose coöperation also was of considerable assistance.

## Travels of Marco Polo

YARKAND is a province five days' journey in extent. The people follow the law of Mahommet, but there are also Nestorian and Jacobite Christians. They are subject to the same prince that I mentioned, the great Khan's nephew. They have plenty of everything, particularly of cotton. The inhabitants are also great craftsmen, but a large proportion of them have swollen legs, and great crops at the throat, which arises from some quality in their drinking water. As there is nothing else worth telling we may pass on."

In the prologue, it is related that the great knowledge and experience of "the world and its wonders" of the Polo brothers' travels of twenty-six years were reduced to writing as indicated by the following quotation:

"Now, being thereafter an inmate of the Prison at Genoa, he caused Messer Rusticiano of Pisa, who was in the said Prison likewise, to reduce the whole to writing; and this befell in the year 1298 from the birth of Jesus."

The travels by the Polo brothers (Marcus, Mofteo), sons of a nobleman from Venice, began from Constantinople in 1260, A.D.

This reference suggests the presence of some form of elephantiasis, and of goiter, with a definite diagnosis that the latter was due to the drinking water.—Grossett and Dunlap, New York. From *Universal Library*, p. 60, chapter 35.

# Identification of Certain Funguses Pathogenic for Man\*

W. D. STOVALL, F. A. P. H. A., AND ANNA BUBOLZ

*State Laboratory of Hygiene, Madison, Wis.*

**B**LASTOMYCOSIS as reported in this country and elsewhere is a disease associated with yeast-like funguses as etiological agents. The term blastomyces is used in a general way to include a multiplicity of organisms, yeast-like in certain stages of their life cycle and under certain conditions, variously described by different investigators as saccharomyces, cryptococcus, monilia, oidium, torula, endomyces and coccidioides. It appears that the term blastomycosis was first used by Busse and later by Gilchrist to designate a skin disease associated with a fungus the identity of which they were not certain.

Since the work of Robin, 1853, a yeast-like fungus has been recognized as the cause of thrush, and these organisms have been described as the cause of vaginitis, bronchitis and certain skin diseases. Primary pulmonary infections have not been frequently observed until recently. From the tropical countries Castellani, Sen, Paramanand and Pijper have reported cases of bronchitis, and in this country Boggs and Pincoffs, Simon, Steinfeld, Johns and Shaw have reported the isolation of yeast-like funguses from the sputum in cases of pneumonia, bronchitis, chronic bronchitis, and asthma. One of us (Stovall), 1928, reported 18 cases of primary infection of the lung with yeast-like fungus.

Concerning the identity of the organisms associated with these diseases there is considerable confusion. The reports indicate a wide variety of organisms which are so sensitive to environment as to defy certain identification. It has come to be believed that any one of these organisms may change its biochemical or cultural characteristics for no apparent reason. Thus it is not uncommon to find in the literature expressions like these: "Asci present but certain strains do not seem to be able to produce asci"; "the characteristics are very variable; some strains of this organism ferment saccharose and some do not." The reports as to the ability of certain of this group to coagulate milk or liquefy gelatin are also variable.

For the past 7 years we have been engaged in the study of the bio-

chemical and cultural behavior of yeast-like fungus isolated from sputum in cases of pneumonia, bronchitis, asthma, and from cases of vaginitis, thrush, skin lesions and generalized infections. In 1929 we reported on 40 strains, and since have completed a study of over 200 cultures isolated by us and others obtained from the American Type Culture Collection. The methods employed have been described elsewhere.

Table I shows the result of the study of the 200 cultures isolated by us. The sugars used are indicated in the table. The results of the fermentation tests were read after incubation at 37° C. for 7 days. The colonies were described and illustrated (Figures I, II and III) at the end of 48 hours at 37° C.

The same malt agar plates used for the study of colony morphology were used to demonstrate the formation of asci. After the morphology of the colony had been observed at the end of 48 hours at 37° C., the plates were allowed to stand in the icebox or at room temperature until dry and hard—from 30 to 60 days. The dried growth was soaked off with sterile salt solution and again plated on malt agar and incubated at 37° C. Numerous asci could be demonstrated after 3 days.

Table II gives a description of the organisms secured from the American Type Culture Collection. Two of the monilia, *M. Albicans* and *M. Candida*, have been the subjects of controversy for a long time, and their characteristics variously described by different investigators.

We secured organisms furnished by two of the most recent investigators, Castellani and Ashford. *M. Richmondi* Shaw and monilia from

Sprue-Zillig were added to give a wide variation of location and opinion by which to test our method of classification.

We have found monilia associated with lesions of mouth, thrush; vagina, vaginitis; and lung, bronchitis, bronchiectasis, asthma and pneumonia. We have encountered them much more frequently than any other organisms. One hundred and fifty of the 200 cultures isolated are some variety of monilia. They are separated from other mycelium producing yeast-like funguses by the size of the cells and mycelium, by the absence of asci and by their method of reproduction—budding and mycelium production. The mycelium is septate and lateral conidia form by budding near the joints of the hyphae, and terminal conidia by budding and constriction at the ends of the hyphae (Figure IV). They also ferment a variety of sugars.

The species within the genus are recognized by colony morphology after incubation for 48 hours on malt agar, by the fermentation of sugars and reaction in milk. Table III shows the different species of monilia which have occurred in our cultures. Instead of recognizing a large variety of species we have been able to classify all the cultures isolated as one or another of 3 species. This is in contrast to previous investigators, who, if they have worked with a large number of cultures, have described many different species in this genus. This multiplicity of species has often been attributed to the variability of the organism under apparently identical conditions. We have not found this to be true. Our cultures have maintained the same reactions after repeated observation over a period of 7 years. When variations have occurred a restudy or checking has revealed an error in technic.

Because our results have shown only 3 different species of monilia and because these results have been so constant, we have studied the organism obtained from the American Type Culture Collection described in Table II. This table indicates that all of these cultures are either one of 3 types of monilia, or because of fundamental biological differences belong to another genus of yeast-like fungus. An instance

TABLE III  
SHOWING DIFFERENTIAL CHARACTERISTICS FOR THREE TYPES OF MONILIA

Species	Maltose	Saccharose	Milk	Mycelial Colonies
Type I	A	A	O	+
Type II ( <i>M. albicans</i> )	AG	A	C	O
Type III ( <i>M. candida</i> )	AG	AG	O	++

of this is *M. Krusei*. This organism is not a monilia but a mycoderma, because of the constant production of a pellicle when grown in the sugar mediums which it ferments. *M. Macedoniensis* Castellani has also been removed from the monilia group and placed in the class of endomyces by us, because asci have been observed repeatedly in this culture. *M. psilosis* Ashford as shown in the table gives constantly the reactions which we consider characteristic of *M. albicans*. Ashford has expressed the opinion that *M. psilosis* represents a single species and that it can be differentiated from *M. albicans*. He admits, however, that while all of his strains ferment maltose, there is a variability in their fermentation of saccharose. This we believe is evidence that *M. psilosis* represents a multiplicity of species, and that in the one instance when saccharose was fermented Ashford was dealing with *M. candida*, and in the other, saccharose not fermented, with *M. albicans*.

The differences between the 3 species of monilia which we have described is still further illustrated in Table IV. Nearly all investigators have described a variety of reactions for these organisms when grown in litmus milk, and some a variability in the same organism. However, a review of the literature shows a striking lack of uniformity in the technic. The length of incubation has varied and no attention has been paid to the reaction of the milk or the constancy of the calcium lactate content. It is well known that various specimens of milk vary in their pH and that autoclaving precipitates the calcium lactate. After this salt has been precipitated the milk cannot be coagulated by rennet and the degree of precipitation slows up the coagulating time of rennet. The failure to take these factors into consideration can explain the variability of these organisms, when grown in litmus milk, reported by many investigators.

In order to substantiate this point of view, we carried out experiments illustrated in Table IV. Skimmed milk tubed in 10 c.c. quantities was sterilized in the Arnold sterilizer at 100° C. for 30 minutes on 3 successive days. To one set of tubes 0.5 c.c. of 10 per cent sterile calcium lactate was added, pH 6.4; another was used as plain milk, pH 6.6; and a third to which NaOH was added to bring it to pH 7.0. The different sets of tubes were inoculated with 0.1 c.c. of a 48-hour glucose broth culture from cultures representative of the 3 species of monilia. This experiment was carried out with all cultures of the different species and with those obtained from the American Type Culture Collection. Table IV shows the reactions constantly observed over many months and in many tests. Whereas we had before experienced the difficulties of other investigators—variability of the reactions of these organisms when grown in litmus milk—we were now always

able to secure the same results and at an almost fixed incubation period. The reaction of the milk at the time of coagulation was determined by removing a small amount from the tube at the time of coagulation, or at the end of 3 weeks' incubation at 37° C., if coagulation had not taken place up to that time. This table shows that organisms in the same species behaved alike, and that the reaction and calcium lactate content corrected the variable results before observed.

The other organisms described in Table I we have not studied so

FIGURE VII—Torula—Culture

FIGURE VIII—Oidium—Culture

intensively. The figures in the plates illustrate the morphological differences of the various organisms. It will be observed that the endomyces is like monilia except that the former produces asci. The torula is similar to *saccharomyces cerevisiae* except that the latter produces asci and the former does not. The cultures of torula will produce abundant mycelium in sugar broth when left at room temperature 3 or 4 months. This is further evidence that uniformity of technic is an important factor in classifying these organisms.

The oidium described in Table I has the same morphological, cultural, and biochemical characteristics as the culture of *Oidium asteroides* Castellani, and the organism reported on by Gilchrist. Figure VIII shows the morphological differences between this organism and the others shown in the same plate. It has much coarser mycelium and a much larger spore with a double contoured wall. It does not ferment any sugar and in tissue never produces mycelium, but spores which are often seen in the giant cells (Figure IX). We have always isolated it from either skin lesions or sputum in cases suffering from a disease similar to that described by Gilchrist. It is our opinion that this is the organism

FIGURE IX—Oidium—In tissue, showing giant cell

which causes the typical blástomycosis described by Gilchrist, and that if the term blastomyces is to be used it should apply specifically to this organism.

#### SUMMARY

In our study of over 200 cultures of yeast-like funguses isolated from cases of thrush, bronchitis, asthma, pneumonia, vaginitis, and generalized infections we have encountered oidia (blastomyces), endomyces, torula, mycoderma and monilia. Of this group we have most frequently encountered monilia—150 out of 200 cultures. Our studies of these cultures and of cultures obtained from the American Type Culture Collection lead us to believe that probably there are only 3 species in this genus, 1 that does not ferment maltose, and 2 that do. Of the latter there are 2 varieties: 1 does not ferment saccharose, a type culture of which is *M. albicans*; the other ferments saccharose and is typified by *M. candida*. We have found the 3 species associated with thrush, vaginitis, bronchitis, etc. The characteristics of these organisms are constant when observed under identical environmental conditions and at stated periods of incubation. We believe that the reported variability of these organisms is due to a lack of uniformity in the technic of the investigators and not to the fickleness of the organisms.

# Monilias, Yeasts, and Cryptococci\*

## Their Pathogenicity, Classification, and Identification

RHODA W. BENHAM, PH. D.

*Laboratory for Medical Mycology, Department of Dermatology, College of Physicians and Surgeons, Columbia University, New York, N. Y.*

SIMPLE fungi reproducing by budding and apparently related to the yeasts have been found with regularity in thrush and tropical sprue, in cases of bronchitis, meningitis, and in a variety of lesions of the skin and its appendages. Similar forms also grow saprophytically on the skin and in the intestines.

In a previous study<sup>1</sup> of such yeast-like forms from thrush, sprue, and skin lesions it was found that certain simple morphological characteristics could be relied upon for grouping them. This morphological grouping could be confirmed by the agglutination method.

### TYPES OF YEAST-LIKE ORGANISMS PARASITIC ON MAN

Most of the strains isolated from a series of cultures which now number several hundred can be classified under 8 types. Strains from oral thrush, intestinal sprue, and from moniliasis of the skin have appeared identical. This type will be referred to as *Monilia albicans*. Three other apparently distinct species of moniliae occur. One species of *Saccharomyces* and one of *Willia* have been found. In addition, strains are found which have been placed in the genera *Cryptococcus* or *Mycoderma*. These strains evidently include several species within each of these genera but no attempt has yet been made to differentiate them.

These types may be defined as follows:

*Monilia albicans* (Robin) Zoph.: Produces a definite mycelium made up of elongated cells which do not readily fall apart; reproduces by buds which accumulate in dense ball-like clusters along the mycelial threads. Globular thick walled chlamydospores are formed, no ascospores. An "inverted pine tree" forms in a gelatin stab. Ferments regularly dextrose, levulose, and maltose with the production of acid and gas. Varies in the reaction on galactose and saccharose. Giant colony, smooth and pasty at first, later convoluted at center, often showing small craters of ruptured gas bubbles. Agglutinates readily in serum produced against a known strain of *Monilia albicans*. Some cross-agglutination with other species,

\*Abstract of paper read before the Laboratory Section of the American Public Health Association at the Second Annual Meeting at Montreal, Canada, September 14, 1931.

but readily separated from these by agglutinin absorption. Agglutinates to full titer in serum prepared against *Monilia candida*. Absorption not yet determined. Pathogenic for rabbits.

*Monilia candida* (Hansen): Similar in morphology to *Monilia albicans* but lacks the characteristic chlamydospores and spore clusters. Produces an atypical "pine tree" in gelatin. Ferments with the production of acid and gas, dextrose, levulose, maltose, and saccharose. Giant colony, membranous and more deeply convoluted than *Monilia albicans*. Cross-agglutinates to the complete titer with albicans serum. Absorption not yet determined. Non-pathogenic for rabbits.

*Monilia parapsilosis* (Ashford): Mycelium more fragile. No chlamydospores, no ascospores. Reproduces by budding. No spore clusters. Forms brush-like structure in gelatin. Ferments dextrose and levulose with the production of acid and gas, saccharose and galactose with the production of acid. Giant colony, pasty, surface smooth or wrinkled or honeycombed. Slight agglutination with albicans serum but separated by absorption. Non-pathogenic for rabbits.

*Monilia Krusei* (Castellani): Mycelium fragile, readily falls apart. Reproduces by elongated buds. No chlamydospores, no ascospores. Short fuzz in gelatin. Ferments levulose and dextrose with the production of acid and gas. Giant colony, flat and smooth. Only slight cross-agglutination with other forms. Readily identified on direct agglutination. Non-pathogenic for rabbits.

*Mycoderma*: Mycelium abundant. Reproduces by oidia or arthrospores, no ascospores. Forms which produce blastospores as well as arthrospores are here provisionally grouped with the mycodermas. Atypical "pine tree" in gelatin. No fermentation of sugars in strains studied. Giant colony rough, membranous, sometimes slight development of aerial mycelium in forms from feces, which is similar to *Oidium lactis*. Not possible to get a good suspension for agglutination. Non-pathogenic for rabbits.

*Cryptococcus*: No mycelium, budding forms only. No ascospores. Nail in gelatin. All strains so far studied ferment dextrose and levulose with formation of acid and gas; some ferment saccharose and raffinose; some produce acid but none gas in maltose. Giant colony, smooth and pasty, occasionally corrugated, similar in appearance to *M. albicans*, usually cream colored. Pink forms also included here. Cross-agglutinates with albicans, candida, and saccharomyces serums. Absorption not yet carried out. Non-pathogenic for rabbits.

*Saccharomyces cerevisiae*: No mycelium, occasionally chains of elongated cells. Reproduces by budding. Ascospores, 1 to 4 in an ascus. Nail in gelatin. Ferments dextrose, saccharose, maltose, and levulose with the production of acid and gas. Giant colony, flat, dry, often with slight radial ridges, brownish with age. Very slight cross-agglutination with monilia serum. Non-pathogenic for rabbits.

*Willia anomala*: Mycelium rudimentary or none. Reproduces by budding. Hat-shaped ascospores, 1 to 4 in an ascus. Nail in gelatin. Ferments dextrose, galactose, and levulose with the production of acid and gas. Colony flat, wrinkled, with radial ridges, dry with age. Cross-agglutinates in *Saccharomyces cerevisiae* serums but separated by agglutinin absorption. Non-pathogenic for rabbits.

#### CONCLUSIONS

Most of the yeast-like microorganisms found in diseased and on normal skin fall within a few species. These may be defined and recognized by their morphology when grown on suitable mediums.

The classification so obtained correlates almost completely with that obtained by absorption of agglutinins.

Direct agglutination is of aid in the recognition of these types. The gross colony characteristics and fermentation reactions are of interest but are often misleading unless studied in conjunction with the microscopic morphology and immune reactions. The relationships of these forms to other species, and hence their permanent botanical classification, cannot be determined on the basis of our present knowledge. Some agreement as to a provisional terminology is, however, necessary to avoid confusion.

One species, *Monilia albicans*, is pathogenic for the skin though it apparently occurs as a saprophyte in the alimentary tract. The other species described are probably non-pathogenic.

1. A detailed study of these forms is to be found in the *J. Infect. Dis.*, 49: 183-215, 1931.

The Typhoid Carrier in New York State

AT the close of the year 1930 there were, exclusive of carriers in state institutions, 244 chronic typhoid carriers upstate under supervision. Only 5 of these were found to have been responsible for cases of typhoid fever during the year 1931, a total of 7 cases having been traced to them.

Thirty-one newly discovered chronic typhoid and 2 paratyphoid carriers were added to the department's list during 1931. Fifty-four of the cases of typhoid fever which occurred in 1931 were traced to 18 of these newly discovered carriers. . . . During the year 22 carriers were removed from the records. Of these 8 died, 5 were released after gallbladder operation and the submission of the required negative specimens, and 9 removed to other jurisdictions. . . . The total number of typhoid carriers on record January 1, 1932, was as follows:

Upstate New York (exclusive of state institutions) .....	262
State Institutions .....	22
New York City .....	275
Total .....	559

Of the 33 new carriers, 12 were discovered through the routine examination of release cultures, typhoid bacilli continuing to be present in the feces a year or more after date of onset of typhoid fever. Seventeen were discovered through routine investigation to determine source of infection of sporadic cases of typhoid fever. . . . Of the 33 new carriers, 23 were females and 10 were males. None of the carriers was under 10 years of age. One carrier, a male, was 10 years old and 1, a female, was 23 years old. Four were from 30 to 39 years of age; 4 from 40 to 49; 9 from 50 to 59; 10 from 60 to 69; and 3 from 70 to 79; 1, a male, was 89 years old.

Of the 33 carriers, 2 were cooks, 18 were housewives, 2 of whom lived on dairy farms and another maintained a tourist home and kept boarders. One was a dairy farmer, and 12 had occupations which did not involve the handling of food.—*Health News*, New York State Dept. of Health, Mar. 21, 1932.

# What Constitutes Health Education in the High School\*

IAGO GALDSTON, M. D., F. A. P. H. A.

*Executive Secretary, Medical Information Bureau, New York Academy of Medicine, New York, N. Y.*

BY a slight change in the intonation of the title of this paper, "What constitutes health education in the High School" may be rendered as either the prelude to an affirmative statement or as the title of an inquiry.

It is my intention, however, to make this paper share in the nature of both an inquiry and an exposition: to question and to tell, the latter in a measure only, what constitutes health education in the high school.

Our inquiry must begin with the high school student. Before tackling the problem of the curriculum in health which should be followed in the high school we must know the nature of its students. Who are they? What is their number? What is their common social and economic position? What is the range of their intellectual capacities?

The answers to certain of these questions may be gathered from a study of the scholastic destinies and of the survival rates of the average 1,000 children entering grammar school.

According to the figures issued by the Education Office of the U. S. Department of the Interior, in 1928, the latest year for which statistics are available, of 1,000 entering the public school for the first time, 974 reach the 6th grade, 855 the 7th, and 768 the 8th and presumably graduate from public or grammar school.

Of the original 1,000, 610 enter high school, 438 reach the 2d year, 321 the 3d year, 268 the 4th year, and 260 are finally graduated from high school, of whom 160 enter college, and 50 are graduated.

To recapitulate, of 1,000 children entering public school, 14.5 per cent do not get beyond the 6th grade, 61 per cent enter high school, but only 26 per cent are graduated; 16 per cent of the original 1,000 or 61.5 per cent of those graduated from high school enter college, and 5 per cent of the 1,000, or roughly 20 per cent of those graduated from high school, also are graduated from college.

---

\* Read at a Joint Session of the Public Health Education and Public Health Nursing Sections of the American Public Health Association at the Sixtieth Annual Meeting at Montreal, Canada, September 14, 1931.

There are approximately 4,250,000 high school students in the United States. Their common age range is 14 to 18 years. They come from, and will continue to constitute, the upper level of the middle class, economically, socially, and intellectually. They may be pictured as representing the hump of the distribution curve of our population; they are the high average.

The intellectual capacities of the high school student may be roughly gaged by his scholastic achievements. His social horizon, his social consciousness, may be assumed to be coextensive if not somewhat wider than that of the group from which he springs.

From a pragmatic viewpoint, therefore, and gaged by the standards current in our democratic nation, the high school group represents an important section of our population—one might almost say, the very backbone of our nation.

It is essential that we should fully appreciate the nature and sociologic position of the high school student, or else we may fall short in our efforts to serve him. The objectives of education being to fit the individual for effective adult life, we need to know the type of adult life which the high school adolescent has foreshadowed. Through such knowledge we may perhaps be better enabled to prepare him to his personal advantage, and to the vast benefit of the community.

We need also to know something of his psychologic stature. We must not approach him as if he were a passively receptive agent amenable to all our machinations. On the contrary, we must appreciate that he has aptitudes, interests, and preferences of his own, some of which are singular to him as an individual, and some characteristic of his age group.

All of these factors we must appreciate and take into account in formulating the answer to the query "What constitutes health education in the High Schools?" for we are not in a position to cut the garment from the whole cloth.

The foregoing is true of every educational approach, but particularly so in the instance of health education. To the factors enumerated there must be added another. The high school teacher of English, for example, knows with a substantial measure of certainty what training in grammar, spelling, composition, and reading the student who comes to him from public school has undergone. His own curriculum can be based on the preceding one and can thus form a continuity with it, but there is no such uniform training in health given to the public school pupil. In fact there is little certainty that the public school graduate has received any appreciable training in health in any form or of any sort. Witness of this may be found in

the widespread ignorance of, and indifference to, the fundamentals of personal hygiene prevalent among them, a condition which makes it necessary that the so-called health education in the high school should consist of campaigns or drives for clean teeth, proper food habits, the correction of constipation, skin hygiene, and the like, which properly belong to the curriculum of the lower 4 grades in public school.

One cannot therefore begin to formulate a program of health education in the high school without taking into account what training should be, but seldom is, given to the students in the public school, and I propose to set the stage, so to say, for the affirmative phase of our inquiry, by indicating what health knowledge and training the pupil entering high school is required to possess in order that an adequate and fitting program of health education may be possible in the high school.

To do this effectively we must divide the life of the student during his public and high school career into 3 periods, based on age and consequent attitudinal differences. The first period lasts roughly from 6 to 10, and takes in the first 4 grammar grades; the second includes the next 4 years, covering the remaining 4 grammar school grades, including at times what is termed junior high school; the third embraces the remaining years of the high school career.

If we divide our student body into 3 groups corresponding to these 3 age periods, we must at once perceive that these groups differ in their needs, in their psychologic attitude, and in their susceptibility to different pedagogic technics. The youngest group is more ready to accept authority. The middle group has the impelling curiosity of the adolescent. The high school group has a budding social consciousness which should be fostered and utilized for health education. The needs and capacities of these groups differ substantially. The youngest is more home-sheltered and less free in making its own choice than the older groups. Its interests are narrower, and its susceptibility to persuasion by science more limited. Its great need is for sound health habits contributing to growth and development. The elements of basic personal hygiene in terms of cleanliness, rest, exercise, outdoor play, and good feeding habits constitute the boundaries of its health interest.

Precept and repetition are effective pedagogic instruments applicable to this younger school group. The *ex-cathedra* statements on the basic needs of the growing child for proper food, rest, exercise and the like are acceptable to them on the authority of the teacher or parent. Scientific expositions beyond the barest simple facts are beyond their grasp and more often serve to confuse than to instruct.

There is little to be gained, for example, in drumming into the heads of children the term vitamins before they have a knowledge of the so-called mechanics of nutrition. They may be taught, parrot-wise, to repeat formulas, but like the parrot they speak without understanding. It is more profitable to confine health education within the immediate needs and grasp of children, and thus to hold and retain their interest and enthusiasm. They are responsive to the pedagogic technics which help build good health habits. Score cards, either personal or class, may be used without offending the nascent individuality of young children. The appeals of emulation, of belonging to the conforming group, of being approved of for doing the right thing, are stronger and more effective with younger children than with the older.

The first group then needs instruction and training in personal hygiene, in proper feeding habits, in cleanliness, in exercise and rest, and in kindred items. Personal hygiene as a cardinal theme in health education is proper in the first 4 grades. In the later periods it should hold a lower rank. If our work with the first age group has been properly done, it should not be necessary to dwell upon personal hygiene as such in the later classes. Some amplification and some modification of the early instruction will be required as the boys and girls grow older, but the groundwork will have been done in the first 4 years of school life.

The second age group, roughly from 10 to 14 years, differs radically from the first. It is less home-sheltered, less willing and less ready to accept without challenge the statement given on the "authority" of parent or teacher, more insistent upon being told why, and being convinced of the reasonableness thereof. The individual in this group exacts a larger measure of freedom in the choice of things, be it clothes, food or friends. He is also self-centered and curious to know about himself and his life. Life crowds in upon his consciousness and he craves enlightenment; he is eager to see the "works" of the machine.

Personal hygiene *per se* has little attraction for this intermediate group, but the construction and workings of the human body are its very meat. Health education should appreciate and meet the needs of this group. Biology, physics, chemistry, and history should converge to enlighten the adolescent on the wonders of the world and on the most interesting machine therein—the human body. In a dynamic, not static, fashion the structure and function of the human body should be taught, with as little insistence on minutiae and as much emphasis on the fundamentals as possible. The larger idea appeals to the young mind. The love of refinement and of details is the reward of maturity.

For instance, it is more important that the adolescent boy interested in the digestive system should know that it is a continuous pipe placed within the body cavity and that in it foods are mechanically and chemically broken down and prepared for absorption, than it is that he should have a knowledge of how to spell esophagus or jejunum. It is not to be understood that a knowledge of scientific terminology is to be disparaged. On the contrary the emphasis is rather on the value of "working knowledge." The first is desirable but this last is fundamental.

In the education of this group in health, the direction should be from the general to the specific, from the whole to the detail. Certain basic ideas on the human body need to be instilled into the consciousness of the young. They should understand that in the biologic sense the human body is a machine, and partakes of the nature of all machines in their subjection to certain universal laws of dynamics. Like all machines the human body does work, and transforms energy in the process. The study of physiology, in this sense, becomes a study of work methods, and that of anatomy a study of machine parts.

Through this method of approach the student may be given a "working knowledge" of the human body. Personal hygiene will of necessity enter into the study, since not only *how* the body works but *how it may work well* must be the theme. But, unlike in the early grades, personal hygiene will not be the primary subject, nor the authority of the teacher the basis for accepting the precepts. Conviction on the merits and value of the rules for proper living will come by the compulsion of scientifically derived conclusions. To this task should be devoted the last 4 years in grammar school, and possibly the first year in high school.

It is with such a training in health that the student entering high school should be equipped. Such training is the essential basis upon which a fitting curriculum in health education might be developed in the high school. Unfortunately, it is but rarely that we find such instruction in our public schools, and as a result our health education in high schools needs so frequently to be of the most rudimentary sort. The situation is truly preposterous; to appreciate it, imagine, by way of contrast, a high school student being taught spelling or the multiplication tables, and yet such is the approximate level of much of the high school health education.

I am leaving out of consideration all of the so-called health work which is carried on in the high schools, because I consider it more in the nature of service than of education. Many confound it with education, but it is no more instructive than any of the other common day

experiences. It is no doubt a distinct advantage to the boy to have his teeth repaired, his vision corrected, his posture improved, and his nutrition bettered, and, indeed, he may learn something about health during the process, but in its entirety this is health work, philanthropy if you please, but not health education. It is a paternalistic service which in a measure has been rendered necessary because we have failed to safeguard the child during its earlier development. It is cure made necessary by our failure to prevent the development of defects. I would not, if I could, put a stop to this work, but I am not willing to allow its inclusion under the heading of substantive health education.

The health education of the high school student should be projected on a higher and broader plane. Heretofore we taught health to the child purely in terms of himself. Now we must teach him to appreciate health in terms of the community and of the race as well. The health education of the grammar school was first made to serve the student's individual growth and development and later his understanding of the fundamentals of the human machine. Health education in the high school must teach the student to understand the nature of disease, disease prevention, and the meaning of health in terms of work, parenthood, and the performance of social and civic obligations.

The high school students differ essentially from their younger brothers and sisters; they are no longer boys and girls but young men and young women. The self-centered interest that served as the *vis a tergo* to his or her little realm has budded into a social consciousness which reaches out beyond the confines of home, school, and immediate family.

An intensified awareness of and interest in the opposite sex brings in its train a bloom of ambition. There is thought of job or profession. There is the deep desire to become a regular fellow, a successful person along the many lines of activity that characterize adult life, and above all there is in this stage of development much wondering as to the what, and how, and wherefore of social and communal life. The narrow interest in self of the childhood period has now been expanded into an interest in the relationship of the self to the rest of the mass. Health education must recognize this condition and utilize it for guidance in the construction of its curriculum and in the choice of its pedagogic technics.

There are aspects to both health education and to the larger health problem which transcend the individual, and have a meaning only when more than one individual is concerned. These aspects, these larger phases, should constitute the vital germ of the high school health education program. It is during this period that we have an oppor-

tunity, and also the obligation, to teach the young man and the young woman the significant health problems which deal with the home and the community, the hygiene of industry, and the health problems that come with adulthood, family life, children, etc.

What a grievous comment it is upon our educational program that many a young man and young woman graduate from our high schools with a tolerable knowledge of geography or of French, and with little or no knowledge of the care of children or the citizen's obligation to coöperate with his community health officers!

The young woman who within, say, 6 or 7 years will be a wife, and perhaps a mother, rarely receives in her high school period a knowledge of the rudiments of dietetics, which, if she but knew and could apply, would contribute so substantially to the maintenance of better health in our families.

The young man who is so soon to take his place in the shop or office receives but little information in the high school to enable him successfully to weather the industrial hazards and those of business environments.

Health education in the high school should take its cues from the realities of life facing young men and women, and be guided by these realities in determining the content of its curriculum. The young woman should understand how much of health depends upon the execution of the social health contract implied in social life; she should understand how the community safeguards its health through appointed health officers and legal ordinances; she should understand the health facts pertaining to motherhood; the basic facts of home care of infants and children should be made available to her; and there should be instilled into her a mental attitude that will enable her to profit by the expert medical knowledge that is available today. Dietetics, home sanitation, and home nursing should be included in her curriculum.

The young man should be taught as much, and in addition should be informed on industrial hazards, shop and office sanitation, and on those practices of personal hygiene, not excluding mental hygiene, which will serve to safeguard his health against the wear and tear of industrial and business life.

This is a large program, but if it be adequately distributed, and properly injected, as it belongs, into the formal studies which today constitute the high school curriculum, it can be executed without undue burden.

What does the high school student study today? Literature, mathematics, science, history, language, civics, biology, hygiene. He also receives a certain amount of physical training. Cannot history be

utilized to teach health? cannot civics include a proper description of the health aspects of communal life? What better end can science serve than to acquaint young men and women with the facts on dietetics, home, shop and office sanitation, and the like? Literature certainly ought to lend itself to health education, and even mathematics could be utilized to the same end.

There has long been a struggle among educators as to the precise meaning of "education." Some have been for the classical tradition, some for the utilitarian. I should loath to subscribe to that extreme utilitarian viewpoint of education enunciated, say, by Spencer, but we must all agree that if education fails to equip the growing boy or girl with the instruments of understanding which will enable him and her to function usefully and to survive, education itself is a failure, and who can deny that health is basic to both useful function and survival?

Though the temptation has been great, I have abstained from composing and presenting to you a detailed plan of health studies. By my understanding of the theme of this discussion, I have felt myself commissioned to analyze and set up criterions on the basis of which it would be possible to organize a detailed plan of study in any high school, and which would fit and allow for any peculiar local situations.

I should like, however, to sketch briefly the major concrete divisions of a plan of studies in health for a high school:

In the first year, corresponding with the junior high school grade, the student's knowledge of the structure and function of the human body should be rounded out. This knowledge need not be detailed and static, but general and dynamic. Even if the student is lacking in the fundamentals, by devoting 2 hours a week for a year it is possible to equip him with a knowledge of the essentials. This phase of the curriculum has been developed in detail.<sup>1</sup>

The second year should be largely devoted to developing a knowledge of disease processes and the means at our command for their avoidance and treatment. Such a study should begin with the general consideration of noxious agents, including germs. The manner in which toxic substances, including bacterial products, injure the body should be made clear. Subsequently, the defensive agents both without and within the body should be detailed; immunological agents such as vaccines, antitoxin, immune serums, and their uses might then be appropriately considered.

In the third year specific diseases should be studied, including those of childhood and their complications, tuberculosis, the venereal, and the degenerative diseases.

In the fourth year home and shop sanitation, home nursing, and

the hygiene, both physical and psychologic, of children, are proper subjects.

Mental hygiene as applicable to the student's person, and as a part of communal existence should be insinuated into the studies during the 4 years. In the last 2 years, special attention should be paid to the problems of work, of love and familial relations, and of friends and communal relations.

As a pedagogic technic the historical approach is particularly effective. It initiates the young into the adult group. It enables them to appreciate their heritage, and the traditions behind them. It serves to enthuse them. By dealing with the history of the development of hygiene, our knowledge of disease and disease prevention, of psychology and mental hygiene, the student is enabled to see in a large way what has gone before, he learns much of the substance of science and, best of all, he has a goal set before him.

# Judging the Efficiency of the Enforcement of Sanitary Milk Regulations\*

JAMES D. BREW, PH. D.

*Milk Specialist, New York State Department of Health, Albany, N. Y.*

THE desire to measure efficiency and progress in any field of endeavor is a commendable characteristic of human nature. These two terms are relative, and different fields of endeavor differ widely in the extent to which efficiency and progress can be measured and expressed concretely.

Much depends upon what our interest is, in attempting to make such measurements. We may be interested primarily in the objective or tangible elements where measurements, expressed in mathematical terms, are usually possible—for instance, the number of miles of improved streets and the like in a given city. Or we may be interested primarily in the subjective or intangible elements where measurements are more difficult, if not impossible—for instance, the degree of illiteracy or of healthfulness among the inhabitants. We find, however, the objective and subjective combined in almost every field, and many people are naturally interested in the evidences of progress in both. The chief danger lies, however, in assuming that the subjective can be satisfactorily measured in terms of the objective.

In the field of sanitary milk control we are confronted with both: the objective, consisting of those tangible, visible and more or less easily measurable items that are recognized as necessary or in many cases desirable in milk production and distribution; and the subjective, consisting of the intangible, and more or less immeasurable end-result—a high quality, safe, palatable product. Any attempt to show progress in the first aspect alone, yields information of unmistakable value only regarding the general status of the conditions surrounding the production and handling of milk. Any attempt to show progress in the second, namely, quality, is commendable but is fraught with many uncertainties. Some of those factors that combine to make up quality are impossible of measurement; the others are, more or less, difficult to measure. With few exceptions, none bear any very close

\* Read at a Joint Session of the Laboratory and Food, Drugs and Nutrition Sections of the American Public Health Association at the Sixty-fifth Annual Meeting at Montreal, Canada, September 16, 1931.

relation to the factors that combine to make up what we may consider as those desirable conditions which merely facilitate the production of quality. The ultimate end-result in milk control in many respects falls little short of being as intangible as that in the field of education, for instance, and is almost as difficult to measure and express in understandable terms. Any attempt to express quality of milk in terms of barns or milk plants is equally as unconvincing and illogical as to express the degree to which a student mastered the subject in hand, in terms of the classroom. All through the history of milk control attempts have been made to devise some method of showing progress, but none has proved convincing, probably because the originators not only failed to appreciate the inherent difficulties but also because they erred in thinking that because a proposed scheme appeared to be logical it must accurately portray the true conditions.

Shortly after 1900, for example, there was unanimous agreement that some mathematical scheme of rating milk control would greatly facilitate the work of health departments. At that time the erroneous theory that disease emanated from the surroundings still had a firm grip upon the prevailing conception of disease relationships; consequently all milk control was directed at the milk producer on the farm. It was felt that if the conditions surrounding production could be sufficiently improved, the problem would be solved. The idea was proposed that there should be some mathematical means of rating dairy barns. It was reasoned that such a rating would stimulate the producer to improve his conditions in competition with his neighbor and that these ratings would also serve as valuable office records for comparing one barn with another or for measuring progress in control. To meet this universally recognized need, the familiar numerical dairy barn score card was devised in 1904 to 1906 and played an important rôle in milk control procedures, particularly during the next decade or so.

The merits of the dairy barn score card were broadcast everywhere. This new method was seized upon enthusiastically by almost everyone. It furnished a mass of figures which appeared logical. So great was the faith in this innovation that control officials finally agreed upon different dairy score limits as a means by which different grades of milk could be defined. In other words, the higher the barn score the higher the quality of milk. It was at this point in the history of control that the original intent of the scoring method was officially perverted. There can be no denying the statement, however, that this method of rating dairies was an outstanding step ahead in bettering milk supplies in general. It had real educational value, and in spite of the fact that

many nonessential items were specified, there were being instituted, as a result, better practices in the handling of milk.

Interest in the numerical dairy barn score has shown unmistakable evidence of decline; particularly during the last 10 years. The reasons are clear and need no detailed elaboration. The producers' and consumers' conception of quality was and still is based upon factors that were a part of the milk itself—flavor, keeping quality, cleanliness and cream line. The conception of quality as held by control officials was and still is confined largely to factors related to public health, sanitation and the like. The dairy barn score in no way expressed either conception. It was the barn that was being rated and not the milk which the consumer purchased.

If a method of scoring anything could be devised that would, at least with a reasonable degree of accuracy, correspond to the public's conception of the thing being scored, then doubtless such a scoring method would be successful. There are certain inherent difficulties, however, which should be kept in mind. For instance, we might score all of the kitchens in a given city and secure data that would be interesting and doubtless instructive, but how many housekeepers would be concerned over the fact that a neighbor's kitchen scored 5 points higher because of an extra window? Then suppose some group of officials—following the precedent established during the first decade of this century in milk control—tried to maintain that the higher the score of the kitchen the better the meals prepared therein. The reaction that would follow is so obvious as to need no comment. Under any present-day plan of rating milk supplies, why should the inhabitants of Podunk be concerned because their milk supply rated 65 per cent while that of Squedunk rated 75 per cent, due to the greater emphasis in the enforcement of certain items which may or may not have had any sanitary significance?

When it comes to comparing the efficiency of the enforcement of sanitary milk regulations, we are confronted with almost insurmountable difficulties. The human element plays such a prominent part. Any group of individuals, for example, might visit a number of dairy barns or milk plants and in general agree that some were absolutely unfit places in which to handle milk, some fair, and some highly satisfactory. But just as soon as they should attempt to express their observations in terms of numerical ratings based upon various items, then the question of the relative importance of the various items would come up. Such decisions are difficult because of differences in opinion and in the end are arrived at arbitrarily. Most well thought out schemes fail to interest the public which does not see the barns that have been

white-washed, or the lack of cement floors, or even the method of cooling or of sterilization and the like. Herein lies one fundamental difficulty in arousing public interest in any rating scheme designed to express progress in milk control.

Wherever the economic aspects in any field are rendered as complex by public health matters as they are in that of milk control, it should be remembered that any attempt to measure progress, is very apt to confront the milk producing and consuming public with questions that prove confusing and which not infrequently entail more or less needless expense. The fact that the average investment per farm dairy throughout the United States is only about \$3,000 (at 6 per cent this allows a yearly income of \$180), indicates some of the real, fundamental limitations. The tendency for too many control officials is to allow their enthusiasm to overrule their judgment and, knowing subconsciously that their position of authority discourages challenge, they are prone to heap upon the shoulders of the milk producer and distributor requirements which have no demonstrable sanitary significance under the claim of potential, public health significance. The inclusion of too many requirements of this nature is in itself bound to lead one astray, even when the most seemingly logical plan of rating progress in milk control is employed.

Some of the difficulties so sure to be encountered in attempting to show, mathematically, progress in milk control by a plan in which is combined both the more or less immeasurable subjective and the measurable objective, is illustrated in the following summary of surveys published in 1930.

Before the adoption of the Standard Milk Ordinance (which occurred in 1923) the raw and pasteurized milk supplies of 152 southern municipalities were about equal in average public health quality to the *present* raw and pasteurized milk supplies of the 183 non-standard ordinance municipalities represented in this survey.

As a result of the adoption of the Standard Milk Ordinance the raw milk of the same 152 municipalities now has a rating of 91 per cent compliance with Grade "A" Raw Milk requirements compared with a rating of 65 per cent for the raw milk supplies of the 183 non-standard ordinance municipalities included in this survey. This represents a superiority of 40 per cent.

This quotation is cited with the sole thought of focusing attention upon some of the pitfalls into which one may be unwittingly led.

Having in mind the rapid increase in the amount of milk being pasteurized, tuberculosis control among cattle, improvements in construction, and in cooling, sterilization facilities, and the like, it is hard to believe that, after 30 years or more of control involving the expenditure of vast sums of public funds, the "public health quality" of

183 northern city milk supplies is no better than that of the 152 southern city supplies. To one who has made an intensive study of milk control policies, who is not committed to any particular ordinance or control policy, and who has seen in every section of the United States all kinds of dairy farms and milk plant conditions—good, bad and indifferent—the following questions are naturally suggested: Is there any conclusive proof to show that the milk supplies of these 183 northern cities are *actually* less safe, more dirty, poorer in flavor, keeping quality or in food value, than the 152 southern supplies? Are the general conditions surrounding production on the farms and handling in the plant less satisfactory? Is this difference, if any, significant? and how is the significance to be proved? Is it not possible that a similar survey, in which the “yardstick” used was based upon the New York State Sanitary Code requirements for Grade A raw instead of upon the Standard Ordinance, would have shown the milk supplies of New York State cities to be, at least, equal in “public health quality,” or perhaps even superior to those of southern cities? Viewing the problem of measuring progress in sanitary milk control from the point of view of the scientist, how are we to know whose “yardstick” is the correct one? Every ordinance written has been based upon the opinion of recognized authorities, and how are we to prove which group is or was the more nearly correct? It is unfortunate that the term “public health quality” was used, because in these surveys it was merely the degree of compliance with the requirements for Grade A milk, as defined in the Sanitary Code, that was being compared.

In another statement in this report is the implication that, as a result of enforcement the consumption of milk in these 152 standard ordinance municipalities increased 21 per cent. Extreme caution should be exercised in drawing any conclusions from data of this nature. According to data recently collected in our own department, the consumption of milk increased over the same period in the State of New York 31 per cent. If “quality” played an important part in increasing the consumption of milk in the south, how is this increase in consumption in the north to be explained?

Efficiency in milk control like the factor of safety in milk supplies, is purely relative. We may have our opinions as to the degree of efficiency in control or of safety in milk, or of the efficiency of any public school system, but when it comes to expressing efficiency in such fields in mathematical terms, we are immediately confronted with a maze of factors, some of which are more or less impossible of measurement, and the significance of some of which is merely a matter of personal opinion.

## LIFE MEMBERSHIP

LAST fall the Committee on Fellowship and Membership started a campaign to induce those in our membership who were qualified to do so to take out Life Membership in our Association. The financial depression made it a bad year for such an undertaking. Nevertheless, the movement has been highly successful, so that we wish once more to bring to the attention of our readers the advantages of taking this step.

On the part of the Association it means a permanent fund from which interest is drawn, thus supplying an income upon which we can depend. It means a decided diminution in fluctuation of membership, which in turn implies a unified body of public health workers upon whom the officers of the Association can count for advice and assistance. It means that we can predict our expenses from year to year with a greater degree of accuracy and an actual saving of office work in that there are fewer bills to be sent out at the beginning of the year, as well as follow-up letters for those who fall in arrears through oversight or for any other reason. A large body of Life Members will give a solidarity and permanence to our organization which can be obtained in no other way.

On the part of members, it means the saving of the annoyance of a bill at the first of the year when so many other dues become payable. For a large majority of our members, it means an actual saving, since

\$100 paid within the course of any given year makes them exempt from payment of dues during the remainder of their lives and assures their membership in the Association. Under the present laws the fee may be deducted from their income tax.

Let us all remember that while it may be hard during a period of depression to pay out \$100, this amount can be remitted in small sums at intervals during a whole year. Only those who have experienced the relief of not having a lot of bills for dues to societies come in on January 1 and each month thereafter can appreciate what it means to be free of them.

The committee have set a goal of 500 Life Members and they are much gratified to see the figure rapidly mounting since the Montreal meeting toward the first hundred. This is an increase of almost 100 per cent over the previous 4 years.

For our own good as well as for the benefit of the Association, to which we owe so much, and to which we are all so devoted, let us make an effort and greatly increase the number of Life Memberships.

### WHAT IS KNOWN ON VITAMIN B DEFICIENCY

TWO laboratories have now announced the isolation of vitamin B ( $B_1$ ) in pure form, Dr. B. C. P. Jansen in Holland, and Dr. Windaus in Germany. The products they describe, however, differ in chemical composition and in physiological activity. Jansen, who first published his method in 1927, has a crystal which contains carbon, hydrogen, nitrogen, and oxygen and is protective against polyneuritis in test rats with a dosage of 0.015 mg. per day. Dr. Windaus's product contains sulphur in addition to the elements reported by Jansen, and is said to be three times as potent.

These discoveries indicate important progress toward chemical identification even though the discrepancies suggest that the goal is not yet attained.

We need more data on vitamin B. Since 1926-1927 when the late Dr. Goldberger and his colleagues first showed that the water-soluble vitamin B of McCollum's nomenclature contained at least two distinct vitamins (now called vitamins B or  $B_1$ , and G or  $B_2$ ) it has become important to delimit the physiological effect of each and their distribution in common foodstuffs.

Water-soluble B is widely distributed in natural foods. When the foods are assayed to determine their relative content of B and G it develops that whole cereals and yeast are rich in B, and relatively lower in G content. Milk, fruits, and vegetables on the contrary have

proved generally richer in G than in B. This fact has led Dr. McCollum recently to comment on the value of his "protective foods" as G supplements to a high cereal diet. The assays, however, also indicate that the B<sub>1</sub> content of the ordinary varied diet may not be as rich in B<sub>1</sub> as we have assumed on the old water-soluble B assay basis.

Dr. McCarrison was the first to suggest the rôle of B<sub>1</sub> in diet and his views have been summarized by Sherman<sup>1</sup> as follows:

B<sub>1</sub> deficiency may result in

1. Impairment of the neuro-muscular control of the bowels
2. Impaired transport of intestinal contents along the canal
3. Impairment of assimilative power
4. Impairment of secretory function
5. Impairment of protective resources leading first to mucous membrane infection and hence to systemic infection

Its relation to anorexia was established by Karr and Cowgill.

More recent work confirms its importance in the regulation of gastrointestinal function and certain types of constipation and colitis.

Such importance as is indicated by the above list need not, however, occasion alarm as to dietary inadequacy in this factor. Acute deficiency in the average American dietary would be rare. Partial deficiency or sub-optimal conditions are probably more common and suggest attention. In the study of these sub-optimal cases the newer discoveries and products promise valuable aid to the clinician and laboratory workers.

## RECORD FORMS

RECORDS for health department service have heretofore been developed by individual cities to meet their individual needs. Lack of uniformity of information and interpretation of services rendered was inevitable. With the rapid growth of health work, the general acceptance of the *Appraisal Form* and the interest shown in the Inter-chamber Health Contest of the National Chamber of Commerce by many of the smaller cities, a demand arose that this condition be remedied.

The forms prepared by the Sub-committee on Record Forms of the A. P. H. A., and now for sale, meet the situation. The needs of the smaller city were kept foremost in mind, a uniform nomenclature and code was adopted, following those believed to be the most universally accepted.

The records drafted demand a minimum of notation, ask no irrelevant questions, and yet contain essentials for the maintenance of service. Standard sizes were adopted to fit standard filing systems and to eliminate waste. In the development of each record, it was referred to active workers in the field for criticism and suggestion. Each record has had actual use in the field and should be satisfactory under most conditions.

Adoption of the records places in the hands of the health officer a means of obtaining facts which will assure him that his department is functioning properly, will point out needed lines of development, and will also be a means of obtaining facts to meet the forces that demand a curtailment in health service.

---

### LETTER TO THE EDITOR

TO THE EDITOR:

On March 19, an Associated Press release was given rather wide publicity throughout the country, quoting me on the "economy budget" of the Chicago Board of Health.

Unfortunately, the reporter's version of the interview contained several statements and implications not in accord with my views and, in my opinion, not consistent with sound public health policy.

Realizing that the article as a whole may prove embarrassing to health officers in other localities, I desire to correct certain of these erroneous impressions and make my position clear in the matter.

The implication that I favor curtailment of present health budgets generally as wasteful or extravagant is a perversion of my statement that health departments unavoidably facing shrinkage of income should curtail at the expense of the less important functions, particularly the refinements of hygiene and sanitation and those activities affecting personal comfort rather than health.

I believe that fundamental health protection should be maintained and even augmented at all costs—during times of economic stress.

My statement in regard to politics in boards of health was simply that, unfortunately, politics does control in some localities and, therefore, has to be reckoned with.

In Chicago we have succeeded in pruning about \$500,000 from our health budget, without grave impairment of essential lines of health protection. We have even provided for increased nursing service, and we have done this largely at the expense of the clerical service and the less important sanitary inspection having to do primarily with the esthetic. This was done in connection with a complete reorganization of personnel.

We are not advocating such cuts—in fact, we deplore their necessity—but we believe that in Chicago we shall be able to carry on the primary essentials, for the time being, without risk to public health.

I feel that health authorities are entitled to some reassurance regarding this interview, and should have available a corrected statement for use in counteracting unfavorable reactions affecting their own budgets.

HERMAN N. BUNDESEN, M.D.,  
*Commissioner, President, Board of  
Health, Chicago*

UNITED STATES CAPITOL—Construction of the hall of the House of Representatives was begun ten years before the first gun was fired in the Civil War, and the Senate chamber wing was started soon afterward. The Capitol is 751 feet long, contains a total of 431 rooms and the cost of construction was \$14,550,000. The Capitol is one of the many old buildings of Washington, and an outstanding example of good architecture. The Corinthian order is used in the external embellishment of the building. Its location "on the hill" is superb and it is one of the most impressive buildings in Washington.

## NEW WASHINGTON

WILLIAM DE KLEINE, M. D., F. A. P. H. A.

*American Red Cross, Washington, D. C.*

VISITORS who come to the national capital will be immediately attracted by one of the most interesting and stupendous projects in public improvement construction work ever witnessed in this country. A \$250,000,000 program of beautifying the city and of erecting commodious buildings to house departments of government is now in progress. Beautiful parks and landscapes with reflecting pools and sparkling fountains; magnificent, massive and monumental buildings—some just completed and others under construction—will greet the eyes of visitors. Those who have not been in the city for a year or more will be surprised and thrilled

by this spectacular development that is destined to make Washington one of the most attractive of all the world capitals.

Those entering the city through the Union Station will see the new Capitol-Union Station Plaza development, which enlarges and beautifies the Capitol grounds. Half way between the Union Station and the Capitol is a new reflecting pool in which is mirrored the dome of the Capitol, and there is also a new fountain.

Facing the Capitol, as a companion building to the magnificent Library of Congress—the largest of its kind in the world—there is under construction the

**LINCOLN MEMORIAL**—The Lincoln Memorial was designed by Henry Bacon and was erected at a cost of \$2,000,000. It was dedicated on Memorial Day, 1922, by William Howard Taft. The memorial is on a circular terrace 1,000 feet in diameter. Stretching to the east of the classic structure are large reflecting pools which mirror the memorial and also Washington Monument nearby. The memorial is a classic Grecian structure with a main hall 70 feet by 60 feet. There is a colossal statue of Lincoln seated in a chair. It was carved from Georgia marble.

new Supreme Court Building which will cost approximately \$15,000,000. Close neighbor to this is the artistic Folger Memorial Library, in which is treasured the matchless Shakespeariana Collection. This is a most artistic building costing \$10,000,000—a new child in Washington's family of magnificent edifices. This library was founded as a repository of rare editions and literary treasures, rather than for the circulation of books. It contains 75,000 volumes collected by Henry Clay Folger during the last five decades of his life. What Mr. Folger himself called "the most precious book in the world," with some 350 other specially valuable volumes, was brought from New York to Washington in an armored car with five guards. This book is the Vincent first folio of 1623, containing the earliest printed version of some of the plays included in the Shakespeare canon. Another collection of outstanding value is the poems in-

cluding "Venus and Adonis" printed in 1599 and valued at \$75,000.

Visitors who heretofore have been whisked away from the Union Station along unpretentious side streets may now approach the heart of the city along a broad new avenue, leading to Pennsylvania Avenue, which is the historic parade ground of the nation. This new avenue goes within two or three blocks of another elaborate development just west of the Capitol—the old Botanic Garden with its up-to-date conservatory, lecture, and exhibition rooms. It also leads to the Mall, which is a large triangular area south of Pennsylvania Avenue extending from the Capitol to the Lincoln Memorial.

The Mall was originally laid out by George Washington and Major L'Enfant as a great central garden for the city of Washington. This area is now being redeemed by the federal government and gradually transformed into beautiful

parks and gardens. Old buildings have been removed and new ones are under construction. What was formerly B Street from the Lincoln Memorial past the Capitol has been straightened, widened and renamed Constitution Avenue. This beautiful avenue connects the Capitol with the New Arlington Memorial Bridge, the new Washington Memorial Highway and Arlington National Cemetery.

Where Constitution Avenue and the new Louisiana Avenue from the Union Station meet Pennsylvania Avenue across the Mall, there has been created "Union Square" as a cross axis of the Mall. This is graced by another beautiful mirror basin comparable with the one between the Washington Monument and the Lincoln Memorial.

Facing the Union Square from the north, visitors may see rising what is designed to be the most magnificent

municipal center in the country. It will occupy four large city squares. It lies directly south of the original Municipal Building, now occupied by the Supreme Court of the District of Columbia.

Across the Mall to the south another large group of government buildings is being erected for the War and Navy Departments. In that part of the Mall triangle, between the Capitol and the U. S. Treasury building, is rising an imposing group of buildings which constitutes one gigantic conception of utility and beauty. Within these buildings will be housed many of the departments of government which for year have been kept in rented quarters and temporary buildings.

One of the greatest new buildings—the Department of Commerce—gracing this triangular area, has been completed and is now occupied. The plans for it

**NATIONAL ACADEMY OF SCIENCES**—The National Academy of Sciences, with its pools and gardens, was designed by Bertram G. Goodhue as a portion of the surroundings of the Lincoln Memorial. It is the place where sightseers may view sunspots and instruments for measuring the almost immeasurable. It represents pure science in the discovery of facts destined to become useful.

were laid when President Hoover was the Secretary of Commerce. He also laid the corner stone. The building is longer than the Capitol and cost about \$17,500,000. Its basement is said to be large enough to store three of the largest ocean liners.

Another great federal structure under way, in which delegates of the American Public Health Association convention will be particularly interested, is the new marble building for the U. S. Public Health Service. It is located on Constitution Avenue not far from the Lincoln Memorial. This building will be ready for occupancy the latter part of 1932 or early 1933. Public health leaders over the entire country will be glad to know that the U. S. Public Health Service will soon come into its own, after having been housed in inadequate quarters for so many years. The recent expansion of the work of the Hygienic Laboratory, now the National Institute of Health, is another milestone

in the progress of public health service and a recognition of its significance in our national and community life.

A close neighbor to the White House is another group of three artistically designed buildings, occupying an entire city square—the headquarters of the American National Red Cross. The last one of this group has been completed and will be occupied in July. The buildings are all of white marble in Grecian style. When the landscaping has been completed and the final touch of the artist applied, this square will be one of the beauty spots in Washington.

A great coordinated development including the Arlington Memorial Bridge, spanning the Potomac, and the Memorial Highway from Washington to Mount Vernon, has recently been completed. This development is intended as an outstanding tribute to George Washington. The bridge is said to be the largest draw-bridge in the world. Huge electric motors operate the two

ARLINGTON BRIDGE—This development has been carried out as a tribute to George Washington. The bridge is 2,150 feet long and cost \$7,000,000. The Arlington Memorial Bridge is said to be the largest draw bridge in the world and the draw opens and closes in 5 minutes. The bridge runs into the new Mount Vernon Highway, said to be the finest piece of roadway construction in the world. With the completion of this roadway, the dream of statesmen for nearly a century has at last been realized.

ponderous 6,000-ton jaws of the draw. The bridge has nine segmental arches of 166-feet span at the ends, and spreads gradually to 184 feet in the central arch. It is 90 feet wide including sidewalks. This makes it almost the width of Fifth Avenue, New York.

The Memorial Highway, stretching for about 15½ miles from Washington to Mount Vernon along a route skirting the Potomac River, was designed by the Bureau of Public Roads of the U. S. Department of Agriculture and intended to be the best example of road building ever undertaken by the federal government.

The national capital has another new structure which is conceded by authorities to be the finest Reptile House in the world. This palace is one of a number of buildings in the Zoölogical Gardens located in picturesque Rock Creek Park. It is attracting scientists and zoölogists from all over the United States and from many foreign countries. This Reptile House combines the finest features of zoölogical gardens in both the old and new worlds. Striking in its architectural splendor, the edifice of Italian Mosaic is profusely decorated both inside and out with colorful stones and with statues and models of odd reptiles of prehistoric and modern times. The interior walls are of marble, the floor is of terrazzo, and the living exhibits are housed in colorful compartments painted and decorated with living shrubbery in a way to simulate the native habitat of these strange denizens of the wilds. Visitors can see here a facsimile of native scenes from the world's outlands.

One of the main attractions of this

famous reptile collection is the 14-foot King Cobra, most dangerous and aggressive of ten species of deadly cobra. It was this famous snake that created so much excitement when it was brought down from the New York Zoo to Washington. It slept in a Pullman berth in a special satchel which its keeper carefully covered with warm blankets to protect its health. This cobra is the presiding genius over this priceless collection of reptiles.

While it is the purpose of this article to stress new developments in Washington, it should be said in passing that there are hundreds of other attractions in the city that are not new. The beautiful Lincoln Memorial and the stately Washington Monument, each standing on a large circular terrace, the Academy of Sciences, the Smithsonian Institution, the Washington Cathedral, the Library of Congress, Mount Vernon, Arlington National Cemetery, the Capitol and the White House, are among the attractions seldom neglected by visitors.

Washington is indeed on the move. It is rapidly taking its place among the most attractive cities and capitals of the world. It has aptly been called a "Paradise of Parks." It is a city of open spaces where peace and comfort are evident on every hand. Visitors who view its constantly increasing wonders will enjoy a peculiar thrill at the thought of citizenship in a country where the ideals of life itself, as well as of individual and community achievement, remain the ever guiding principles that determine the destiny of the nation.

NOTE: The materials for this paper were provided by the Greater National Capital Committee of the Washington Board of Trade.

# ASSOCIATION NEWS

## WESTERN BRANCH A. P. H. A. THIRD ANNUAL MEETING

THE Western Branch of the American Public Health Association was organized in 1928, and with the sanction of the parent body, the American Public Health Association, has increased its membership to over 1,600 during these 4 years. Its purposes are to offer western public health people opportunities for exchange of experience, interchange of views with our eastern colleagues, and in general to promote western public health development.

Three major items of special western importance will be included on the program at the Denver meeting: Psittacosis, now apparently endemic in native western birds of the parrot family, to be discussed by Dr. Karl F. Meyer of the Hooper Foundation, San Francisco; reciprocal relations for the control of shell fish in Pacific ports to be discussed by the state health officers of California, Oregon, and Washington; Rocky Mountain spotted fever, with special reference to its similarity to

typhus, discussed by Dr. R. H. Riley, Health Officer of Maryland. Several national as well as western public health problems will be discussed by both eastern and western authorities.

The meeting is to be addressed by Dr. Louis I. Dublin, President of the A. P. H. A. The presiding officer will be Dr. E. T. Hanley, City Health Officer of Seattle, President of the Western Branch. Other national authorities who have accepted invitations to appear on the program are: Dr. John Ferrell, President-elect, A. P. H. A.; Dr. E. L. Bishop, Chairman of the Executive Board, A. P. H. A.; Dr. Kendall Emerson, Acting Executive Secretary, A. P. H. A.; Dr. Taliaferro Clark, Acting Surgeon General, U. S. Public Health Service; Dr. H. W. Hill, Professor of Bacteriology, and Nursing, and of Health, University of British Columbia, Vancouver; Dr. M. P. Ravenel, Editor, *American Journal of Public Health*, and others.

## NEW MEMBERS

*The following list includes applicants who have been approved for membership in the A. P. H. A. by the Sub-committee on Eligibility. These new members have requested affiliation with the sections indicated, and action by the Section Council will follow.*

### *Health Officers Section*

Richard Binion, M.D., City Hospital, Milledgeville, Ga., Chairman, Baldwin County Board of Health

Tillman C. Britt, M.D., P. O. Box 605, Washington, N. C., Beaufort County Health Officer

Everett E. Carrier, M.D., Dyer County Health Unit, Dyerburg, Tenn., Director

Frank B. Clark, M.D., Gainesboro, Tenn., Director, Health Unit District 2

Preston H. Edwards, Jr., M.D., Franklin, Tenn., Assistant Health Officer, Williamson County

W. K. Fishburne, M.D., Moncks Corner, S. C., Director, Berkeley County Health Department

Ross L. Gauld, M.D., Jonesboro, Tenn., Assistant Director, Washington County Health Department

Edwin B. Gute, M.D., 5630 N. Lake Drive, Whitefish Bay, Wis., Health Commissioner

O. P. Hampton, Jr., M.D., 6801 Delmar Blvd., University City, Mo., Health Commissioner  
 Thomas H. Haynes, 516 West Vine Ave., Knoxville, Tenn., Director of Public Welfare

Robert D. Hollowell, M.D., Health Unit, Blountville, Tenn., Assistant Medical Officer, Sullivan County

Robert H. Hutcheson, M.D., Murfreesboro, Tenn., Assistant County Health Officer, Rutherford County Health Department

Wilson W. Knowlton, M.D., Rm. 546, State House, Boston, Mass., State District Health Officer

Marriott T. Morrison, M.D., 4705 Washington Ave., St. Louis, Mo., Chief Physician, Venereal Clinic, Department of Health

L. E. Viko, M.D., Public Safety Bldg., Salt Lake City, Utah, Health Commissioner

#### *Laboratory Section*

Carlos Bou, Department of Health, San Juan, P. R., Assistant Serologist

Luis S. Davila, P. O. Box 403, San Juan, P. R., Assistant Bacteriologist

Rollin W. Hoyt, 352 Western Ave., Boston, Mass. (Assoc.)

Dr. Jose Marques-Torres, Department of Health, San Juan, P. R., Pathologist

Americo Serra, M.D., Ponce, P. R., Director, Ponce Branch Biological Laboratory

#### *Vital Statistics Section*

Anna M. Scholfield, City Registrar's Office, City Hall, Providence, R. I., Statistician

#### *Public Health Engineering Section*

Alberto P. Amarante, C.E., Av. Afonso Pena No. 2524, Belo Horizonte, Brazil (Assoc.)

J. Lashley Johnson, State Department of Public Health, Nashville, Tenn., Sanitary Inspector

Robert McK. Clouse, Franklin, Tenn., Sanitary Inspector

Philip L. McLaughlin, Ohio Water Service Co., 59 Lincoln Way E., Massillon, O., Division Sanitary Engineer, Federal Water Service Corp.

Ira D. Ogle, Sumner County Health Unit, Gallatin, Tenn., Sanitary Inspector

#### *Food and Nutrition Section*

Rex D. Bushong, D.V.M., Department of Health, Nashville, Tenn., Associate Milk Specialist, U. S. Public Health Service

#### *Child Hygiene Section*

Franklin M. Erlenbach, Jr., D.M.D., 358 Commonwealth Ave., Boston, Mass., Clinician, Brookline Public Schools

#### *Public Health Education Section*

John W. Amesse, 624 Metropolitan Bldg.,

Denver, Colo., formerly President, Denver Public Health Council

Grace J. Blank, Chandler Court, Williamsburg, Va., Instructor in Public Health and Physiology, College of William and Mary  
 Isabelle F. Borden, M.D., State Education Dept., Albany, N. Y., Supervisor, School Medical Inspection

Herman E. Cohn, 1341 W. Madison St., Chicago, Ill. (Assoc.)

Julia L. Cummings, State Office Bldg., Hartford, Conn., Secretary, Connecticut Tuberculosis Committee

Myrtle Curnutt, 542 Fifth Ave., New York, N. Y., Director, General Health Bureau

John L. Fuller, Department of Biology and Public Health, M. I. T., Cambridge, Mass., Assistant

Allan J. Hrubby, M.D., 1130 N. Lorel Ave., Chicago, Ill., Secretary, Board of Directors, Chicago Municipal Tuberculosis Sanitarium

Rosa Kuntz, Dresden, Tenn., County Nurse

Edward L. Markthaler, M.D., 1513 State St., Santa Barbara, Calif., Director, Health Education, State Teachers College

F. B. Morgan, State Department of Health, Nashville, Tenn., Associate in Health Education

Margaretta A. Smith, 237 Thompson St., New York, N. Y., Assistant General Director, Judson Health Centre

#### *Public Health Nursing Section*

Mary Bedford, R.N., Trenton, Tenn., Supervising Nurse, Gibson County Health Department

Myrtle T. Cross, R.N., Franklin, Tenn., Public Health Nurse, Williamson County Health Department

Velma DeMoss, R.N., Trenton, Tenn., Public Health Nurse

Nina E. Garrison, R.N., Franklin, Tenn., Public Health Nurse

Frances F. Hagar, R.N., Murfreesboro, Tenn., Chief Nurse, Rutherford County Health Department

Mrs. T. O. Hall, Box No. 12, Dayton, Tenn., County Public Health Nurse

Maude Hodge, R.N., Erwin, Tenn., Public Health Nurse

Margaret McC. Johnson, 516 W. Vine St., Knoxville, Tenn., Director, Knoxville Public Health Nursing Service

Martha P. Kelly, R.N., 904 Fair St., Franklin, Tenn., Public Health Nurse

Ora P. Moore, R.N., Trenton, Tenn., Public Health Nurse

Mrs. Nell T. Pearson, R.N., Humboldt, Tenn., Public Health Nurse, Gibson County Health Department

Mrs. Carrie K. Reynolds, Sumner County

Health Department., Gallatin, Tenn., Public Health Nurse

Ruth Skelley, R.N., Franklin, Tenn., Public Health Nurse

Roane Thornton, Gainesboro, Tenn., County Public Health Nurse, District 2

Archie Weatherly, Waverly, Tenn., Humphrey County Health Nurse

Josephine M. Wright, Gainesboro, Tenn., U. S. Public Health Service, Trachoma Prevention

#### *Epidemiology Section*

Jane N. Baldwin, M.D., Vassar College, Poughkeepsie, N. Y., College Physician

Irvin W. Sander, M.D., 1512 St. Antoine St., Detroit, Mich., Student (Assoc.)

#### *Unaffiliated*

Joseph H. Bishop, 157 E. Norwich Ave., Columbus, O., Student (Assoc.)

W. Compton Wills, 16th & French Sts., Wil-

mington, Del., Chief Engineer, Board of Water Commissioners

#### DECEASED MEMBERS

Peter H. Bryce, M.D., Ottawa, Ont., Canada, Elected Member 1883, Fellow 1922

Henry H. Brinkerhoff, M.D., Jersey City, N. J., Elected Member 1918, Fellow 1923

Louis Shapiro, M.D., Bangkok, Siam, Elected Member 1922, Fellow 1923

Mrs. M. W. Ainsworth, R.N., Sioux City, Ia., Elected Member 1928

John O. Polak, M.D., New York, N. Y., Elected Member 1929 (Assoc.)

Vinton A. Selby, M.D., Clarksburg, W. Va., Elected Member 1924

Joseph P. Yaffe, M.D., Boston, Mass., Elected Member 1930

O. I. Bemis, M.D., Modesto, Calif., Elected Member 1931

## LETTER FROM GREAT BRITAIN

### THE VALUE OF THE TUBERCULIN TEST

THE subject of tuberculosis appears to have received quite a marked amount of attention from investigators in this country recently. Within a few weeks of each other there have been issued two official publications, one from the Medical Research Council and the other from the Ministry of Health.

The former is a report by Dr. D'Arch Hart, Assistant to the Medical Unit, University College Hospital, London, while the latter is described as "A Report on Tuberculosis, including an Examination of the Results of Sanatorium Treatment," by Dr. MacNalty, Senior Medical Officer for Tuberculosis, in the Ministry of Health.

Dr. Hart, in his report, gives the results of tests performed upon a large number of clinically tuberculous patients of all ages and types of infection, and in contrast with these the effects following tuberculin tests applied to an almost equal number of clinically non-tuberculous individuals of all ages.

Many interesting observations are based upon the observations made, some of them being of real value and importance. Chiefly, Dr. Hart finds himself in a position to assert that the tuberculin test is one of scientific accuracy, though he qualifies this by saying that it is only so if the intracutaneous (Mantoux) test is used.

For the von Pirquet cutaneous test he has practically not a good word to say so far as reliability is concerned. Positive reactions, Dr. Hart warns, are not as yet capable of distinguishing an active tuberculosis from "the benign results of infection that has at some time or another been implanted in most members of an urban population."

The error in the case of the negative reaction being only about 2 per cent, its diagnostic value need not be questioned. This is particularly so in the case of children who have not become sensitized to tuberculin by chance exposure to infection. The possibility suggests itself that the test may be of real value from the preventive point of view by indicat-

ing the need for securing protection for individuals in households where a tuberculous patient has been living.

One of the beliefs Dr. Hart claims to have shattered as a result of his observations is that tuberculous infection is universal in later childhood among the poorer classes or general population of urban communities. This view was based upon the results of some of the prominent earliest tuberculin surveys, but in the case of London and some European and American cities appears to be untenable, as many as one-third or more of the clinically non-tuberculous children now being found to react negatively to the intracutaneous test at the age of puberty.

#### TWENTY YEARS OF TUBERCULOSIS SCHEMES

DR. MacNalty, though described as Senior Medical Officer for Tuberculosis, has interests and activities very much wider than this title would suggest. The work he has done in relation to diseases of the central nervous system is very well known, particularly his official reports on encephalitis lethargica. These and his lectures as Milroy Lecturer of the Royal College of Physicians in 1925 on epidemic diseases of the central nervous system, indeed, have secured for him a reputation that has extended far beyond the boundaries of Great Britain.

The possibility that this report on tuberculosis may go some way towards enhancing that reputation is not impossible, for, though ostensibly he treats of the problem from the local point of view, any study of tuberculosis and any information submitted with regard to it must have a wide application and call for attention from everybody concerned in dealing with the disease.

Dr. MacNalty's primary object has been to carry out a survey of the work done in relation to tuberculosis since the more or less general establishment

of anti-tuberculosis measures by local health authorities. As something like 20 years have elapsed since this happened, this would seem an appropriate time for making such an examination. The system adopted is an interesting one, and the ground appears, so far as can be judged by present-day lights, to have been very properly and completely quartered.

Figures that suggest that there is a decline both in incidence and mortality are set out, though a statement, bluntly made, that "there are no accurate figures available in regard to incidence of tuberculosis in England and Wales," is likely to startle and even annoy those complacent ones—of whom there are probably many—who cannot imagine any schemes with which they are associated doing other than superlatively.

The system of notification has been in operation for round about 20 years and, like any such system, works very much more satisfactorily as a means of providing information upon which preventive action can be based than as a method of providing amusement for the statistically minded. For these latter the death rates are a more accurate and fruitful source of entertainment. In the case of tuberculosis, to the preventive officer they afford gratification also, revealing that between 1901 and 1929 the standardized death rates per million have fallen from 1,807 to 932.

In his report, Dr. MacNalty explains fully the methods that have been followed and that may be taken to have assisted in bringing about this result. Having examined these carefully, the conclusion he arrives at is that "the diminishing figures of tuberculosis year by year afford great encouragement to anti-tuberculosis work and proof of its value." And of sanatorium treatment, the results of which he set out to investigate, he finds himself able to say that it is the most effective method of treating the disease.

As a contribution to the literature of tuberculosis and a review of practice in relation to the preventive treatment of the disease, Dr. MacNalty's report has very much to commend it.

SIR WILLIAM R. SMITH

BY the death of Sir William R. Smith, which occurred rather suddenly on March 17, public health and preventive medicine lost a figure of some prominence. Though he had never actually held a post as medical officer of health, he was responsible for the training and teaching of large numbers of those now in office in various parts of the world. One of his claims was that it was he who was primarily responsible for having it made law that before an individual could be appointed to such a post he must possess specified qualifications.

The Royal Institute of Public Health, of which he was Principal and, in fact, the founder and central figure, provided full courses of training for such qualifications. In addition, it functioned as a learned society dealing particularly with preventive medicine, and provided facilities on a commercial scale for carrying out chemical and bacteriological investigations for local authorities and others.

Sir William Smith enjoyed something of an international reputation, which he owed mainly to the fact that his Institute made a practice of holding an annual conference, choosing commonly as the venue some university city outside the British Isles.

In addition to British medical and legal qualifications and honors, Sir William Smith had numerous foreign degrees, honors, orders, medals, and decorations of extreme brilliance conferred upon him. A man of great energy, he took part in a vast variety of work, and was a member of an infinity of public

bodies, sharing fully in all their activities up to the very day of his death at the age of 83.

Probably the Royal Institute of Public Health was his favorite concern, and as he was its moving spirit and was engaged in providing a new home for it when he died, there exists some uncertainty as to what the future is likely to be. To any who knew him it seems impossible to believe that anybody like him or able to fill his place will ever be found.

#### THE SEDGWICK MEMORIAL LECTURE

THE invitation to Dr. W. G. Savage, County Medical Officer of Health of Somerset, to deliver the Sedgwick Memorial Lecture for 1932 at Boston, has given very great pleasure here. Dr. Savage is one of the more prominent of the county medical officers of health in England, and has devoted very much more time than any of his colleagues to laboratory and research work.

It was while he was Medical Officer of Health of Colchester that he began this work with investigations into questions relating to food, and since then he has continued research in this direction, and has contributed very largely to the common stock of knowledge.

He has made a number of special investigations on behalf of the Ministry of Health with regard to bacterial food poisoning and such like subjects, and as an authority on milk—the county of Somerset being one of the milk producing counties—he is extremely well known.

At the moment he is not, I think, connected with any teaching institution, but he has held a number of special lectureships, and commonly, I believe, has chosen some subject having reference to food bacteriology and food poisoning.

London CHARLES PORTER, M.D.

# PUBLIC HEALTH ADMINISTRATION

**Diphtheria Prevention in New Jersey**—An attractive and interesting report has been issued of the 3-year state campaign for the prevention of diphtheria conducted by a committee representing the State Medical Society, the State Board of Health, the State Board of Education, the State Health Officers' Association, the Anti-tuberculosis League, and other organizations. The work was highly organized under a central executive council. A publication committee prepared lectures and passed upon literature used throughout the state. A press committee of representative newspaper men was chosen, and the use of these names on the news releases, which were periodically sent out from the distribution office of the committee assured a general use of the material.

Two major policies of the committee were that the campaign should be as far as possible guided by physicians, and should be conducted as largely as possible on a voluntary basis without the expenditure of large special funds appropriated or otherwise secured for the purpose. At least monthly meetings were held.

Among the activities were included the preparation of three standard lectures, to professional groups, to lay audiences, and for radio talks, and the use of 500, 24-sheet billboard posters of a diphtheria film trailer, of 5,000 attractive posters for doctors' offices, of monthly news articles, of a series of campaign letters, and of much other literature. Chairmen of 21 local committees were carefully selected medical men.

During the year following the organization of the committee, the State

Department of Health reported about 125,000 children immunized in public clinics. Thirteen counties reported 212,150 children immunized during the first 2 years, two counties indicating that 75 per cent and 77 per cent of their children respectively were protected. Sixty-nine lecturers gave 258 talks before a combined audience of 53,465 during this period.

It is noteworthy that during the third year, emphasis was placed on the protection of the preschool child. It was concluded that if the disease were to be eradicated by the protection of children before school entrance, it would be necessary to increase public clinic service or to secure a corresponding increase in the interest and participation of physicians in private practice. New literature and activities were developed in order to further personal education and contact with parents of preschool children in order to convince them of the need for this protection.—Three Year Report, Committee for the Prevention of Diphtheria, F. J. Osborne, Chairman, Health Officer, East Orange, N. J.

**Preventive Measures in Illinois**—The volume of preventive practice, in relation to the prevalence of certain diseases subject to control through vaccination and diagnosis by laboratory procedure, increased very noticeably in Illinois during 1931, according to statistics available from the State Department of Public Health.

The amount of toxoid and toxin-antitoxin distributed by the department indicates that 21 children were immunized against diphtheria for each case reported in 1931 against 16 to 1 in 1930

and 11 to 1 in 1929. For each case of smallpox 54 people were vaccinated in 1931 compared with 15 per case in 1930 and 21 per case in 1929. Against typhoid fever 20 people were vaccinated per case in 1931 compared with 21 per case in 1930 and 12 per case in 1929.

The diagnostic laboratories of the department examined for typhoid fever 13 specimens per case reported in 1931 compared with 9.5 per case in 1930. For diphtheria there were 2.5 specimens per case examined in 1931 compared with 1.4 per case in 1930. For tuberculosis the rate was 1.5 specimens per case in 1931 and 1.4 in 1930. For these three diseases 40,155 specimens were examined during 1931 against 35,984 although the aggregate number of cases reported declined from 18,997 in 1930 to 16,667.

Racine, Palo Alto, Milwaukee, and Detroit—The first four annual reports to be received for the calendar year 1931 are from these four cities, each of which was an honor city in the U. S. Chamber of Commerce Health Conservation Contest. These annual reports are not cluttered with long tiresome statistical reports but contain a few figures, sufficient to show the trend in mortality, morbidity, and birth rates, and present the reader with a clear conception of the type of service being rendered.

The death rates per 1,000 population were unusually low; 9.0 for Racine, 9.4 for Palo Alto, 9.1 for Milwaukee, and 8.8 for Detroit. The Health Commissioners ascribe the low rate to a number of circumstances, among which are the absence of epidemics of influenza and pneumonia; the favorable climatic conditions, with no extremes of heat or cold; the fact that people are leading more normal lives, indulging in simpler foods, securing longer hours of sleep, and relieved of some of the hazards of industry; and last but not least the fact that the programs of health education

are taking root and stimulate a responsive consciousness in the mind of the average citizen which has brought about a higher rate of protection against diphtheria and smallpox, a more frequent health examination, and more general practice of the simple regulations of personal hygiene.

The Health Commissioner of Milwaukee sounds a note of warning to the effect that although the tuberculosis death rate in each city has shown a marked decrease, there are many whose resistance has been lowered by worry and an inadequate food supply, and in the near years to follow this may result in a higher tuberculosis incidence. He feels that the foundation for an increase in the tuberculosis death rate of future years was laid in many homes during 1931.

In Detroit, in 1931, there were 13,403 deaths with a rate of 8.8, based upon an estimated loss in population of 70,000. Had the United States estimate of population been used, the death rate would have been even lower. This is the lowest rate in the history of the city. The birth rate was 18.6; the infant mortality rate 57.0; 47 per cent of births occurred in hospitals; 96.2 per cent of births were attended by physicians. Suicide and appendicitis for the first time appeared among the 10 principal causes of death, having taken the place of the acute communicable diseases and diarrhea and enteritis.

In Milwaukee, in 1931, there were 5,354 deaths. Had the rate of 1910 continued, there would have occurred 7,500 deaths. The yearly saving over the rate of 1920 is 1,505 lives. The infant death rate was identical with that of Detroit, 57.0. It is noted that there were 624 non-resident deaths in the city compared to 872 resident deaths outside of the city. Apparently tuberculosis cases are being hospitalized outside of the city limits as there were 22 more resident deaths from tuberculosis out-

side of the city than the average number for the 5 previous years.

In Palo Alto, there were 136 deaths, a rate of 9.4; there were 148 new babies with only 2 deaths, an infant mortality rate of 13.5.

In Palo Alto, there were reported but 2 cases of diphtheria with no deaths. In Milwaukee the incidence of this disease continues to decrease, there being 126 cases reported with 11 deaths. Detroit also saw a new low mark for diphtheria with 96 deaths or a rate of 6.3 which is less than one-third of the average for the preceding 5 years. Practically all communicable diseases showed new low records in Detroit. The typhoid death rate was less than 1; the tuberculosis death rate was reduced by more than 10 per cent over the preceding year; there were only 2 deaths from measles and a new low rate was established for scarlet fever. In Milwaukee, there were but 11 cases and 2 deaths from typhoid fever, a rate of 0.34.

Medical participation and coöperation continue to be the keynote of progress. In Detroit, all diphtheria preventive work has been continued through the agency of the family physician, resulting in protection to approximately 70 per cent of the children between the ages of 6 months and 10 years. Medical participation has been extended into the tuberculosis program with the establishment of a case-finding plan. A group of coöperating dentists has also been established. In Milwaukee, the medical profession has worked in close coöperation with the Health Commissioner.

There were two absorbing new interests in the Racine Health Department: first, the Health Department moved into its new and commodious quarters; and second, with the coöperation of the County Medical Society, a new program was undertaken to reduce the maternal mortality. In Racine, particular emphasis has been laid upon the educa-

tional features of health work. The Health Commissioner has been very active in radio broadcasting and has worked out unique methods of presenting his material in the form of dramatic episodes. The infant mortality rate was 36.2 per 1,000, the lowest that the city has ever experienced. The diphtheria death rate was 4.4, which is the same as for the preceding year.

These health department reports are to be commended for their simplicity, timeliness, and their general appeal to the serious minded citizen.

#### Serving the Small Community—

The 13th annual report of the Commonwealth Fund states that the major programs have one common characteristic in that they rely upon the interplay of selected social factors to accomplish ends which the exclusive use of a single approach would be less likely to attain. In public health work, the Fund is aiding in the work of the small general hospital, the rural public health unit, and the professional service of the rural physician.

Through the hospital, its function is broadly defined and its work is flexibly directed, a sheaf of educational influences can be brought to bear upon both physician and layman which, in the long run, may revolutionize the philosophy of rural medicine and the practice of community health.

Emphasis was given during the past year to better administration within the hospitals and to the development of plans for out-patient service. The 50-bed hospital is considered economically justified only if it is a compact unit, functioning smoothly with a small and well trained staff. In the 6 hospitals supported by the Fund, the increase in average occupancy during the year was 12 per cent—from 21.2 to 23.8, against a theoretical maximum of 50. The experience of small hospitals indicates that an average occupancy of approximately 35 would be normal for a 50-bed unit.

Direct educational activities associated with the hospital program—institutes for physicians and nurses, and postgraduate fellowships for physicians and dentists—were continued.

A fivefold program of rural medical service and rural health has been developed in which the small town general practitioner plays a central rôle. In the three states of Tennessee, Massachusetts, and Mississippi the activities were as follows:

1. Fellowships to enable rural physicians to do postgraduate work (15 to each state)
2. Provision for the strengthening of the teaching of preventive medicine in the undergraduate medical school
3. Scholarships to encourage the preparation of promising medical undergraduates for rural practice (5 to each state)
4. Intensive development, as a demonstration for other communities, of public health service on a county or town-union basis (2 units in each state)
5. State-wide advisory service, through a traveling unit of the state health department, in the development of rural public health service generally.

It is believed that a really progressive health department cannot reach its objectives unless the health officer thinks of himself, and the local physicians think of him, as a colleague of the general practitioner, specializing on certain forms of health service which involve communal action, and acting as a general consultant on the broadly educational phases of medicine. Through a division of health studies, efforts are being made to evaluate health work in terms of measurable results in separate fields of activity and to examine critically the evidences of progressive integration.—*Ann. Rep.*, Commonwealth Fund, 1931.

**Cincinnati Health Federation**—The chief concern of the Public Health Federation during 1931 was the mobilization of the health resources of the community to forestall, so far as might be, the probable ill effects of adverse

economic conditions. A minimum food budget was prepared with the help of physicians and nutritionists and distributed to all organizations caring for needy families. A second evaluation of the county health department activities was completed. A study was made of facilities for medical care of sick poor.

A joint committee of the Academy of Medicine, the Dental Society, the Better Business Bureau and the Federation has devoted itself to the task of trying to protect the public from fake and misleading medical advertising.

Assistance was given the Anti-Tuberculosis League in sponsoring a bond issue for the expansion and remodeling of the tuberculosis sanatorium. A cancer control council is made up of physicians and surgeons, dentists, nurses, health educators, and lay people.

A campaign of education is carried on through the medium of the newspapers, the radio and lectures to various clubs and societies. Comprehensive reports of several other public health councils indicate the broad scope of work of the Federation.—*Fourteenth Ann. Rep.*, Public Health Federation and its Councils, Cincinnati.

**Maternal and Child Welfare Work by the Public Authorities, Germany: Prussia**—The last annual report of the Ministry of Public Welfare of Prussia for 1929 gives an account of the maternal and child health work done in that country by the government. The report discusses the work of 348 prenatal health centers in that country for the examination of expectant mothers. Almost 19,000 women were examined in Berlin alone in the last fiscal year; one-fifth of them showed pathological conditions, but with repeated examinations it was possible to improve their health and to prevent complications. The majority of municipalities and rural communities provide financial aid in cases of poverty, in addition to the maternity

benefits paid under the federal laws. About 3,700 infant health centers were maintained with public funds, and they reached about two-thirds of the 700,000 children born annually in Prussia. A larger proportion of children are cared for at the centers in the cities than in the rural districts.

In many cities the work of the infant health centers extends to children of preschool age; in other cities special centers are provided for such children. About 400,000 children were reached by the centers reporting to the Ministry of Social Welfare. The public authorities also maintain large numbers of kindergartens and other arrangements for children of preschool age, such as day centers, rest homes in cities and in the country, clinics for ultra-violet ray treatments, and lunch rooms.

According to the report the health work extends to a larger proportion of school children—3,000,000 out of 3,600,000—than to children of other ages. Almost 3,200 school physicians and 4,600 school nurses were employed in the last year. Dental service has been given in the great majority of public schools; of the nearly 2,000,000 children whose teeth were examined in 1929, 44 per cent were found to be in need of treatment. School lunches were served to half a million children in about one-fifth of the public schools in Prussia. The municipal authorities are also maintaining a large number of rest homes and vacation homes for school children, and more than 600,000 children were thus accommodated in 1929.—*Archiv. f. Soziale Hygiene und Demographie*, Berlin, Vol. 6 (Sept.), 1931.

## LABORATORY

### A MODIFIED CELLOBIOSE BROTH FOR THE DIFFERENTIATION OF *B. COLI* AND *B. AEROGENES*

JOHN E. DOWD

*Assistant Director, Pease Laboratories, Inc., New York, N. Y.*

CELLOBIOSE was first proposed as a medium for the differentiation of *B. coli* and *B. aerogenes* by Jones and Wise<sup>1</sup> in 1926, and was very carefully correlated with other mediums by Koser.<sup>2</sup> It was later used by Lewis and Pittman<sup>3</sup> and by Perry<sup>4</sup> and probably others.

The authors of the method, Jones and Wise, used this sugar in a concentration of 0.5 per cent in a broth containing 0.3 per cent Difco beef extract and 1 per cent Difco peptone. It was sterilized in an autoclave for 20 minutes at approximately 121° C. They do not

tell how acid production was determined.

Koser, in his study of the method, added 0.5 per cent of cellobiose to a standard meat extract, peptone medium, plus 0.5 per cent agar, plus bromthymol-blue (pH range 6.0 to 7.6) in the amount suggested by Baker<sup>5</sup> (12 c.c. of a 0.2 per cent alcohol solution per liter). It was put into small tubes, in 2 to 3 c.c. amounts, and sterilized in an autoclave. This made a soft agar which was inoculated by stabbing with a straight wire. Gas production was detected by the torn appearance of the

agar medium and acid formation by the change in the indicator, brom-thymol-blue (blue to yellow). Incubation was at 30° C. for 48 hours as a routine procedure.

Lewis and Pittman employed Koser's method. Perry used the same soft agar method and, to a limited extent, broth fermentation tubes. The concentration of cellobiose used was 0.5 per cent and brom-thymol-blue was employed as an indicator for acid formation. A 4-day incubation at 37° C. was used. He says of it: "The cellobiose test has been found the most satisfactory single test for this purpose" (differentiation of *B. coli* and *B. aerogenes*).

In the method here reported the medium used was a standard sugar-free broth containing 0.3 per cent of beef extract and 0.5 per cent of peptone (Armour's bacteriological). To each 100 c.c. of this broth was added 0.25 gm. of cellobiose (Difco) and for an indicator of acid formation, 0.875 c.c. of a 0.05 per cent solution of brom-cresol purple (pH range 5.2 to 6.8). It was tubed in very small fermentation tubes and sterilized in an Arnold sterilizer, 45 minutes on 3 successive days. (The experience of Jones and Wise and Koser indicates that it can safely be autoclaved.) The regular inner tubes (8 mm. inside diameter) of the Dunham fermentation vials were used as the outer tubes. For inner tubes, glass tubing of about 5 mm. outside diameter was cut into 3/8" lengths and these sealed at one end. One c.c. is sufficient medium for one of these fermentation tubes.

In the first trial of this medium a concentration of 0.5 per cent of cellobiose was used. In a later batch a concentration of 0.25 per cent was accidentally employed and as the lot of medium apparently worked just as well, this concentration was adopted. (It was stated by the authors of the method that a lower concentration of the sugar might prove equally satisfactory.)

21. Feces—Montgomery....	—	—	+	—

It has been employed many times as a differentiating medium in studying the growths on Levine's Eosin Methylene Blue Agar, transfers being made by means of a straight wire from separate colonies on the plate. Incubation is at 37° C. Acid and gas formation with *B. aerogenes* is rapid, easy to observe, and frequently positive in 24 hours. In 48 hours the results are usually final. In only a very few cases were the results indeterminate, that is, acid + and gas — or acid — and gas +.

It was found to work with great uniformity of results on pure cultures of *B. coli* and *B. aerogenes* freshly isolated from feces. A few correlations were made with Koser's citrate and with Eijkman's dextrose broth at 46° C. incubation. The accompanying table shows a selected list of these results. There are included a few that do not show perfect correlation. They indicate quite definitely that this medium may be depended upon to give results that are in line with those found by Koser and others.

At \$6.00 per gm. for cellobiose the cost for this constituent is only \$.015 per tube. With a reduction in the price of this sugar in the market, which may reasonably be expected, this obstacle in the way of its more general use would be removed.

#### SUMMARY

The cellobiose broth of the authors, Jones and Wise, has been modified by the reduction of the concentration of cellobiose to 0.25 per cent and the addition of brom-cresol purple as an indicator. The cost has been reduced by tubing in micro tubes that require only

1 c.c. for filling. Gas and acid formation are rapid and definite and sufficient correlation study has been made to indicate that the same results are obtainable as those found by Koser, who noted excellent correlation in the case of the two well defined sections of the group, with several other differentiating mediums, particularly with citrate broth, and also with the known source of the culture.

ACKNOWLEDGMENTS—The author wishes to acknowledge the assistance of George H. Chapman of the Clinical Research Laboratory of New York in supplying freshly isolated pure cultures of *B. coli* and *B. aerogenes*, also of Marjorie S. Clapp and Priscilla Johnson, bacteriologists, who performed the laboratory work of the study, here reported.

## PREPARATION OF MEDIUM FOR THE CULTURE OF BACTERIUM TULARENSE

R. E. DANIELS

*Division of Laboratories, Ohio Department of Health, Columbus, O.*

LABORATORY workers have experienced some difficulty in growing *B. tularense*. This is especially true when the organism is cultured on a large scale for the preparation of antigen where the addition of blood to the medium is undesirable.

The following method of preparing the medium has proved satisfactory in the laboratory. The ingredients pres-

ent and the quantities used are those recommended by Francis, but the method of preparation has been modified somewhat.

Beef infusion broth is prepared in the usual manner with the addition of 1 per cent peptone and 0.5 per cent NaCl. This is titrated and the reaction adjusted to pH 7.3. The broth is then sterilized for 15 minutes at 15 lb. pres-

sure, cooled, filtered and titrated again. Any needed correction in reaction is made and the broth again sterilized at 15 lb. for 10 minutes. It is then titrated a third time and the reaction again corrected to pH 7.3 if necessary. With each sterilization the change in reaction becomes progressively less and often no correction is necessary after the third titration.

It was found that subsequent sterilization did not change the reaction and that additional titrations of the medium were therefore unnecessary. It is this drift toward the acid phase which, if left uncorrected, probably accounts for more failures in the culture of *B. tularensis* than any other one factor. While this method is suggested for *B. tularensis*, it should be equally applicable to any organism that has similar requirements of a definite and constant pH value.

After the third titration and correction, 2 per cent agar, 1 per cent dextrose and 0.1 per cent pulverized cystine

are added to the broth. The medium is distributed into large bottles or into test tubes, depending on whether it is to be used for stock cultures or for growing the organism for antigen. The medium is then given a final sterilization at 15 lb. for 20 minutes.

For antigen production we use 1 liter prescription bottles, adding 150 c.c. of the medium to each bottle. For stock cultures rabbit blood is added to the tubes under aseptic conditions.

The agar in the large bottle is agitated just before it is cool enough to solidify. This is desirable, as the cystine, being insoluble, settles out with any precipitate which may form during sterilization. Each bottle is placed on its flat side and allowed to solidify. The flat surface thus exposed is inoculated in the usual way. *B. tularensis* grows on this medium with an odor resembling freshly cooked meat. Any sour or musty odor is in itself proof of contamination even before it is confirmed by stained preparations.

# VITAL STATISTICS

## ACCIDENT CLASSIFICATION PROBLEMS IN NEW YORK STATE

EDMUND SCHREINER

*Assistant Director, Division of Vital Statistics, State Department of Health,  
Albany, N. Y.*

AS the New York State Health Department reports contain data for the entire state it was necessary, upon adoption of the last revision of the *International Classification of Causes of Death*, that this department and New York City employ a common code. New York City had been tabulating in detail statistics of fatal accidents—especially transportation accidents. Since they wished to continue, we agreed to code the following types: accidents in mines and quarries, by machinery, or by means of transportation without reference to the *International List* and to present these deaths in a supplemental table under the numbers used therein.

It is quite simple to code "machinery," "mines and quarries," and "transportation" accidents, but to classify the same by the International number presents a question—whether to code as a "crushing accident" (No. 186) or "other accidents" (No. 194). New York City Health Department assigns most automobile accidents, where a fracture is involved, to "crushing" (No. 186), but the U. S. Bureau of the

Census informs us such cases should be coded under Title 194 unless crushing is definitely stated. This department desires to agree with the Census, but our figures should be comparable with those of New York City.

A death certificate, covering an automobile accident, seldom specifies "crushing," but in many instances states fracture of portions of the body, and, when death results from overturning or collision with another vehicle or pedestrian, "crushing" is a logical conclusion.

Old No. 185 (falls) and old No. 188 (accidental traumatism by other crushing) would be comparable to new No. 186 only if most transportation accidents were included therein. Of 928 accidental deaths in the first 6 months of 1931, we assigned 837, or 90 per cent, to Title 186.

The question to be settled is: Where no definite statement of "crushing" appears on the certificate, or where it cannot be obviously deduced, should vehicular accidental deaths with fractures be assigned to No. 186 or No. 194?

## VITAL STATISTICIANS AND THE SAFETY MOVEMENT

R. L. FORNEY

*Statistician, National Safety Council, Chicago, Ill.*

THE safety movement recognizes that made real progress in the past few years  
registrars of vital statistics have in the collection of data on accidental

deaths. Only one state is now missing from the registration area; death reporting in the registration states is becoming more complete; the new standard death certificate provides for more information on accidental deaths; and the new *International List of Causes of Death* shows great improvement in the accident classifications.

Vital statisticians, however, are just on the threshold of helping and influencing the safety movement. The work done so far is fundamental and basic. The plans have been made and the foundations laid. Now, the time has come to start building the information that those interested in accident prevention need so badly, and which is available from no other source. The United States and Canadian registrars should develop this information with 3 things in mind: uniformity, simplicity, and timeliness.

We have uniformity, of course, in the accident classifications of the *International List*. In addition to this we must also have uniformity of definition for industrial, home, and public accidents.

In mentioning simplicity I have in mind that there is need for a simple one-dimensional classification of accidental deaths which, with cross classification by age, can be shown on a single sheet, which will be intelligible to the ordinary person, and will contain the essential data about accidental deaths. Such a sheet is being given you in connection with this paper. On the reverse side of the form, also shown, are the definitions of industrial, home, and public accidents. Certain registrars have been preparing a form approximately like this for several years—Alabama, Kansas, North Dakota, New York, Ohio, Missouri, and perhaps others.

The third element of a useful reporting procedure is timeliness. Many state health departments now issue monthly bulletins; the U. S. Bureau of

the Census has current releases on automobile accidents and other items. Vital statistics should provide a running record of mortality information which will guide the day-to-day and month-to-month efforts in behalf of health and safety. To accomplish this purpose it is desirable that this meeting go on record as favoring the preparation of a report of this kind monthly by the state registrars.

The principal purpose of such a summary would be to arouse and maintain interest within the state. In most states we find safety councils, women's clubs, schools, etc., all interested in accident prevention from a state-wide point of view. These organizations would appreciate the efforts of the state registrar in preparing the information; and the influence and prestige of the health department would be enhanced by such services. Such summaries could also be collected from the various states and summaries could be prepared that would have national significance.

#### ACCIDENTS SIXTH IMPORTANT CAUSE OF DEATH

It is unnecessary to stress the importance of the accident problem. In the country as a whole, accidents are the sixth most important cause of death. In some of the states represented here they lead the list, and among others are in second or third place. Among men accidents are the second most important cause of death in the entire country. Among children from 5 to 14, accidents cause twice as many deaths as any disease. The safety movement, therefore, appeals to vital statisticians on sure grounds.

Public health officials have a real responsibility in the safety movement, and the first and fundamental thing they can do is to obtain and summarize the facts about accidental deaths, and then present them to the public on a uniform, simple, and timely basis.

Important!

(Fill in blanks)

In addition to the.....motor vehicle deaths in public places, shown above, there were.....fatalities involving motor vehicles in homes and work places, making a grand total of.....motor vehicle deaths. Of this grand total, .....were of persons gainfully employed at the time of the accident.

(Please see reverse side for Instructions and Definitions)

National Safety Council, Gen. Stix, 1, 12-31-2M

REVERSE OF FORM

INSTRUCTIONS

For cities this report is intended to cover all deaths that result from accidents occurring in the city. Deaths in the city that result from accidents occurring outside should not be included. But deaths occurring outside the city as a result of accidents within the city should be included.

For states the report should cover all accidental deaths occurring in the state regardless of where the accident occurred. The exceptions noted above for cities are less important for states and should therefore be disregarded.

In either cities or states THE INFORMATION NECESSARY TO COMPLETE THIS REPORT CAN BE OBTAINED ONLY FROM THE RECORDS OF THE REGISTRAR OF VITAL STATISTICS. Police departments or others who can expect to get complete information on traffic accidents only will be supplied with a different form, on request to the National Safety Council, Inc., 20 N. Wacker Drive, Chicago. The traffic accident form provides for a detailed analysis of fatal, non-fatal, and property damage accidents and their circumstances.

DEFINITIONS

A. INDUSTRIAL ACCIDENTS.  
This classification includes all accidents arising out of and in the course of gainful employment unless injured person was a domestic servant; or was operating, riding in, or struck by a land, air, or water vehicle. However, when such a vehicular accident occurs in a railroad shop or yards, or other industrial work place not open to the public, it remains in the industrial classification.

B. HOME ACCIDENTS.  
This classification includes all accidents occurring wholly within domestic premises (within the building, lot or apartment lines of any domicile) except when the injured person was a gainfully employed person other than a domestic servant.

C. PUBLIC ACCIDENTS.  
This classification includes all accidents other than those described in Sections A and B. This group of public accidents is separated into two parts: (a) Accidents involving a motor vehicle; (b) Accidents not involving a motor vehicle.

KEEPING THE PUBLIC INTERESTED IN ACCIDENT DATA

EARLE G. BROWN, M. D., F. A. P. H. A.

*Secretary, Kansas State Board of Health, Topeka, Kans.*

THE Kansas State Board of Health during the past 3 years has made a special study into the cause and also the possibilities of the prevention of accidental deaths. The reason for this study was the definite increase from year to year in the number of accidental deaths which occurred in the state. In the past 6 years, in only one have accidental deaths been less than 6 per cent of the total, and in 1930, 8.3 per cent of the 19,583 deaths were charged to external causes.

The old form of standard death certificate did not provide for any informa-

tion in regard to deaths from external violence. The new form provides for the inclusion of this, if the questions are answered on the certificate. If these questions are answered on all such deaths, it is possible to classify them as to the place of origin and the type of accident. The new standard form does not allow for the inclusion of some of the data which our department is collecting.

We have found six principal sources for the distribution of material in regard to accidents and their prevention: (1) the press, (2) the radio, (3) safety

speakers, (4) city and county health officers, (5) safety chairmen of the American Legion, and (6) safety directors of various types of utilities and industries.

The newspapers have made liberal use of accident material prepared by the State Board of Health. Thirteen summaries were prepared on accidental deaths in 1930, and received wide distribution through the public press.

Our department has available the service of a broadcasting station for a 7-minute broadcast each week. During the past 5 months we have prepared and had broadcast, with an estimated

audience of 4,000,000 persons, 4 papers on fatal accidents reported during 1930. As a response, we have received a request from a utility company for a copy of one of these in order that it might be mimeographed and distributed to the employees of this company, which operates in 9 states.

The public is interested in accident prevention and will give careful consideration to material which is prepared and presented in an attractive manner.

---

NOTE: These three abstracts are of papers read at the Special Session on Accidents of the Vital Statistics Section of the American Public Health Association at the Sixtieth Annual Meeting at Montreal, Canada, September 16, 1931.

## PUBLIC HEALTH ENGINEERING

### MODERN METHODS OF RODENT CONTROL

C. K. STEWART

*Director of Rodent Control, Health Department, Los Angeles, Calif.*

LOS ANGELES is a modern city and appreciates its responsibility to the world commerce that enters its harbor. It created some years ago the Division of Rodent Control as a part of the city's Health Department. Mindful of the losses that many cities of the world have suffered from rodent-borne diseases, in times past, Los Angeles wages a constant warfare against all rodents. The Division of Rodent Control is now functioning with a personnel of 13 inspectors, trained in the habits of rodents and capable of prompt and intelligent action at the right time.

In a city of 1½ million, and comprising 465 square miles of territory, the task of eliminating the rodent population is indeed a difficult one. In addition to depleting their number approximately 5,000 per month, this division maintains a monthly index, ever

holding itself in readiness as an efficient nucleus of a larger, adequate force in the event of an emergency. If a department of health is to protect and safeguard the public properly, it must maintain such a unit. This applies especially to seaport cities where vessels arrive from all parts of the world.

This division has succeeded, since its inception to the close of the fiscal year for 1931, in capturing 159,522 rats; 60,297 mice, and 8,295 ground squirrels, demonstrating conclusively the correctness of the extermination methods adopted. These rodents are tagged, showing species, sex, and the address where picked up, and promptly delivered to the rodent laboratory, where they are subjected to various tests to determine if they are capable of conveying any contagious disease. No estimate is made or even attempted of

the great number of rats and squirrels destroyed by the distribution of poison baits and the use of carbon bisulphide. In addition to trapping, poisoning, and shooting of rats and squirrels, and with a view to better sanitary conditions in and practical rat-proof construction of all food establishments, personnel of this division inspect all such food depots and pass on them, before permits are issued.

The work of a rodent control unit of any health department, having at its front door a world harbor with a cargo movement of \$100,000,000 a year, and maintaining a water front of 25 miles, must be expedited by using the latest approved scientific methods. Control work at the harbor is handled by inspectors quite as astute as the rodents themselves, for with vessels arriving from world ports, even a bandicoot may be expected to escape from one of these ships and find its way ashore. Under existing ordinances coastwise shipping does not come under rigid inspection, excepting when a vessel arrives from a known plague or suspected plague port. Ships from foreign ports are met upon arrival, day or night, by inspectors whose duty it is to see that all lines leading from ship to shore are equipped with approved rat guards; that gang planks are lighted when not in use; and that all crated, burlap wrapped cargo is inspected and the consignees' addresses are forwarded to the office in order that the shipments can be inspected at the time of uncrating or unpacking.

Thanks to modern construction, the wharves at the harbor are built of concrete and the buildings are practically rat-proof, thus facilitating the work of rodent control to a marked degree.

In the eradication work the wharves and a distance of 1 mile from the water front are spread with poison at least once a month, also a line of traps to catch any stray rats that might have

escaped from a vessel is kept constantly working under the wharves and in the warehouses. This service, together with the periodical flea survey and the monthly index, affords excellent protection.

The officials at the harbor are to be commended for their untiring efforts in aiding in this all-important work; they are most certainly anti-rat propagandists, and with their coöperation with the local office, rats are being kept to a minimum at this port.

The downtown business section of the city is divided into districts of approximately 4 square blocks, with 1 inspector in each district. He runs 300 official snap-traps daily to supply the laboratory with specimens and to keep up a monthly index of the migration of the rodent population. Scout trappers cover the outlying districts, answering all complaints from home owners, furnishing expert instructions on rat-proofing, rodent destruction, and abatement of rodent nuisances.

Much progress is being made in rodent destruction through coöperation with the Chamber of Commerce and other city departments. For example, the Building and Safety Department furnishes this division with the address of all buildings (at the time permit is requested) to be moved or demolished, thus enabling us to process them with poison baits, destroying all rodents therein, and preventing a spread to the surrounding buildings when these structures are removed to different locations or torn down.

Routine work in the control of ground squirrels entails poisoning, shooting and gassing of them throughout the outlying sections of the city, and is carried on by a squad of 4 inspectors. These men supply the laboratory with specimens and also furnish the material for an excellent ground squirrel index.

A close study of the flea index discloses the fact that fleas appear to be

more prevalent on the ground squirrels during the months of March and April of each year, some animals producing on combing from 30 to 75 fleas each, with *Ceratophyllus acutus* predominating.

In conclusion, it is believed that the work of this division affords the best means of blocking off the entry of rat-carried diseases, and thereby contributes its bit to the protection of the public health.

Los Angeles possesses anti-rodent laws in its General Sanitary Code, parts of which are herewith given:

*Sec. 43—Bakeries*—All floors, walls, ceilings, and entrances shall be so designed and constructed as to exclude rats, mice, vermin, flies, and other insects.

*Sec. 74—Par. B—Restaurants*—All floors, walls, ceilings, and entrances shall be so designed, constructed and maintained as to exclude rats, mice, flies, and other insects.

*Sec. 104—Meat Markets*—Every meat market or meat shop, and every room, building, or place in which meat, fish, game, poultry, or any product thereof is stored, held, kept, exposed or offered for sale for food for human consumption, or manufactured into articles of food for human consumption, shall be so constructed and maintained as to prevent any flies or other insects or any vermin or rodents from entering therein.

*Sec. 144—Par. C—Poultry Slaughter Houses*—The walls of any such room or place wherein any such rabbits, chickens, turkeys, ducks, geese, and other fowls are slaughtered

shall be constructed of cement or asphalt, or any such room or place shall be lined with metal to a height of 6 feet above the floor thereof.

*Sec. 208—Par. A—Food Sanitation*—The floors, walls, and ceilings of such places shall be well constructed of smooth, cleanable material and so designed, constructed, and maintained as to exclude rats, mice, vermin, flies, and other insects.

*Par. G*—All articles of food or ingredients thereof used in the manufacture, preparing or mixing of any kind of food products shall be kept thoroughly covered and protected against contamination of any sort, including dirt, dust, rodents, flies, and other insects.

*Par. I*—All portions of such buildings or premises, including yards, alleys, areaways, waterclosets, plumbing, dressing rooms, utensils, tables, equipment and parts thereof, shall be kept clean, sanitary, and free from dirt or accumulation of rubbish, garbage, refuse, or debris of any sort; suitable garbage and rubbish receptacles shall be provided and kept clean, covered, and in good condition.

*Sec. 356—General Sanitation*—No rubbish, waste or cast off materials of any kind shall be placed, left, dumped, or permitted to accumulate or remain in any building or place, or on any premises so that the same shall or may afford food or a harboring place for rodents. Every place, room or building where any article of food or products thereof is stored, held, kept, given away, exposed, or offered for sale for human or animal consumption shall be so constructed and/or maintained as to prevent rodents from entering therein and from harboring therein or thereunder. All buildings, places and premises shall be kept by the owner or agent in a clean and sanitary condition and free from rodents.

colorations, the degree being largely dependent upon the amount of oxygen present. So far as is known the enzymes are merely inactivated by freezing. These difficulties have led to studies of wrapping and packaging methods, whereby oxidative and other deteriorative changes are kept at a minimum. While it is true that rapidly frozen foods contain relatively small crystals immediately after freezing, it is not generally known that these grow during storage. This is particularly noticeable in brined products. Fluctuations in temperature are especially serious in this respect and may cause considerable loss in quality. The temperature must therefore be under delicate control and maintained at about 10° F. or lower.

Transportation is another problem not yet fully worked out. Balsa wood, or thick waxed corrugated fiber board cartons, lined with moisture proof paper and heat sealed, serve as excellent insulators and are extensively used for shipping products which do not contain much free juice. Such containers will keep the contents in good condition for 3 to 4 days. Refrigerated cars are used for long distance shipments. Carbon dioxide ice has been used during transit and is very effective. It is also used to keep retail purchases of frozen food in good condition for several hours. Greater care is necessary with frozen plant products than with flesh foods because enzymic action, breakdown and leakage begin at lower temperatures in the former. In any case the consuming public should have assurance that the freezing, storage, and transportation are effective and under control, and that frozen foods offered for sale have not been previously thawed.

#### EFFECT ON NUTRITIVE VALUES

Freezing *per se* has little effect on the nutritive properties of foods. The relation of leakage or "drip" to physical changes has already been discussed.

Richardson and Scherubel,<sup>2</sup> in 1908, were among the first to find that very little chemical change occurs in frozen meats. Their findings have been amply verified by C. S. Smith,<sup>3</sup> Clark, Almy and Pennington,<sup>4</sup> and Almy and Field.<sup>5</sup> Taylor<sup>6</sup> and Birdseye<sup>10,20</sup> studied the effects of freezing on animal and plant tissues and concluded that the only significant changes which occur are histological and physical, and these can be largely eliminated by the use of suitable processes and equipment.

The investigations of Birdseye,<sup>10,20</sup> Taylor,<sup>6</sup> Woodroof,<sup>11</sup> British Food Investigation Board,<sup>12</sup> The Council for Scientific and Industrial Research in Australia,<sup>13</sup> Joslyn,<sup>14</sup> Classen,<sup>15</sup> Low Temperature Experiment Station, Cambridge, England,<sup>16</sup> Diehl and others<sup>17,18</sup> have proved

the feasibility of freezing a wide range of foods with retention of good quality, flavor and eye-appeal. The conditions of packing, suitability of varieties or species, proper storage temperatures, and effect of thawing have been studied. If the juices of frozen foods are retained and eaten, there would appear to be no loss in valuable extractives. The darkening and oxidative changes which occasionally occur are of importance principally because they affect appearance and palatability. Very little research has been conducted on the nutritive value of frozen foods. Vitamins A, B, and D are uninjured by freezing.<sup>20, 21</sup> The fate of vitamin C after thawing is more uncertain, especially when stored for long periods of time. Delf<sup>21</sup> working with orange juice, and Bracewell, West and Zilva<sup>22</sup> with apples, found little loss resulted from freezing storage. Our own studies<sup>23</sup> on cranberries indicate a considerable loss when held in air at 10° F. for a year. Much research is needed on the effect of freezing and storage on the vitamins. It seems likely that some losses in vitamin C would occur, should defrosted fruits and juices stand for any considerable time.

#### EFFECT ON MICROORGANISMS

Very little information is available on the number and character of the microorganisms in frozen foods. The writer recently made some determinations, shown in Table I. Except in the case of fish and beef, which were brine frozen at 10° F., the other foods were frozen in air at —10° F. in sealed tin cans. Examinations were made after approximately 12 months in freezing storage at 10° F. Good quality fresh products were used for these experiments. The original bacterial count was not taken.

Presumptive tests for *B. coli* made for each sample were all negative. Corn, peas, and beans yielded cultures resembling *B. aerogenes* and *B. cloacae*. Many pinpoint colonies were present on the plates made from the peas and corn after thawing. The varieties of bacteria were relatively few. Though not carefully counted, molds were fully as numerous as bacteria in the fruits, but the standard methods agar is not a particularly favorable medium for molds. Yeasts were present in moderate numbers. Irish and Joslyn<sup>24</sup> have demonstrated the resistance of yeasts to freezing storage. Fruits packed with sugar had fewest organisms of all. Upon thawing, the greatest increase occurred in the fruit frozen without sugar. Except for a little surface discoloration, the sugar packs were in good condition after 36 hours, while fermentation and surface molding were observed in all samples not containing sugar.

Though the initial bacterial population of the frozen vegetables and

TABLE I

MICROÖRGANISMS IN FROZEN FRUITS, VEGETABLES AND OYSTERS, AND IN THE SAME FOODS AFTER STORAGE FOR 24 HOURS AT 70° F.

Product	Bacteria per gram Frozen	Anaerobes in 10 grams	Bacteria per gram after storage 24 hrs. at 70° F.	Anaerobes after 24 hrs.	Odor
Raspberries—with sugar 3 : 1	3,000	—	8,000	+	good
Raspberries—cardboard box	270,000	+	3,600,000	+	"
Raspberries—cardboard box	8,000	—	850,000	—	"
Strawberries—cardboard box	10,000	—	27,000	—	"
Strawberries—cardboard box	8,000	—	160,000	—	"
Strawberries—with sugar 2 : 1	200	—	2,000	—	"
Peaches—sliced, cardboard box	50	—	600	—	"
Peaches—sliced, with sugar 3 : 1	60	—	700	—	"
Cherries, sour pitted with sugar 3 : 1	0	—	20	—	"
Peas—blanched	8,000	+	29,000,000	+	sour
Peas—blanched	less than 1,000	—	24,000,000	+	"
Green beans blanched	less than 1,000	+	40,000,000	+	abnormal
Green beans blanched	2,000	—	30,000,000	+	sour
Sweet corn blanched	5,000	+	100,000,000	+	putrid
Sweet corn blanched	1,500	+	60,000,000	+	putrid
Carrots blanched	3,000	+	5,800,000	+	abnormal (no gas)
Carrots	less than 1,000	—	3,600,000	—	abnormal
Oysters	22,000	+	320,000,000	?	sour

oysters was small, a tremendous increase occurred within a very few hours after thawing. There was a loss of characteristic odor in about 6 hours, followed by souring and finally decomposition. Cocci, sporulating aerobes and a varied flora were present. The thawed vegetables and their juices make an excellent culture medium for bacteria, and unless held at very low temperatures soon spoil and become unfit for food. This is an important point which should be emphasized.

Frozen foods must be plainly labelled "Perishable," especially if sold in tin containers, so that the public will not treat them in the same way as the well known heat-canned foods. For this reason, it has been suggested that sealed tin cans be not used for frozen foods," but they have so many advantages that this is scarcely feasible. Aside from its convenience, air-tightness, and ability largely to eliminate oxidation and flavor losses, the sealed can swells or bulges when the contents spoil. As in heat-canned foods, this swelling will serve notice on the housewife that the contents are not safe to eat.

Under the anaerobic conditions existing in the sealed can, spores such as *Cl. botulinum*, if present, may readily develop and form toxin, particularly after thawing has begun. It is not believed that appreciable bacterial growth would occur in the very short time required to

freeze small packages; besides some oxygen is still present in evacuated cans for several days after sealing. The oxygen present in the tissues and in the interspaces of foods gradually combines with the metals of the can. Paper or cardboard cups and boxes are not airtight; hence danger from toxicogenic anaerobes probably is not present in foods frozen in this type of container.

Poultry is usually frozen whole. Fish may be frozen in the round, dressed, or boned and filleted. The latter method has found decided favor with the housekeeper. Meats are also being extensively retailed in wrapped, attractive packages. Though extensively consumed for a great many years, no serious outbreaks of disease or illness have been proved to be caused by frozen meats, fish, or poultry. They are packed in small paper boxes and often wrapped with cellophane. So long as the packages are kept frozen no difficulty need be anticipated, but upon thawing, leakage and decomposition may occur.

A few data (Table II) were obtained on the bacterial content of frozen fish, poultry, and beef, (1) after having been frozen a year, and (2) after thawing for 24 hrs. at 70° F. The products were wrapped in waxed paper and packed in small paper boxes holding about 1 lb. Freezing was carried out at -10° F., and storage at 10° F.

TABLE II

BACTERIA IN FROZEN MEAT, POULTRY AND FISH AND IN THE SAME FOODS AFTER STORAGE AT 70° F. FOR 24 HOURS

Product	Bacteria per gram Frozen	Anaerobes per 10 grams Frozen	Bacteria per gram after 24 hrs. at 70° F.	Anaerobes Thawed 24 hrs.	Odor
Beef Steak	390	—	1,400,000	—	sl. abnormal
Pork Chops	1,300	—	8,700,000	+	sl. sour
Haddock	38,000	—	770,000	—	normal except slight NH <sub>3</sub> odor
Salmon *	20,000	—	330,000	—	lack of fresh odor
Whole chicken (breast)	0	—	30	—	fresh
Eggs (in tin can)	190,000	+	70,000,000	+	sour, tainted odor

\* The salmon had been previously frozen.

After defrosting for 24 hours, the eggs were of poor quality bacteriologically; the meats, fish, and chicken were excellent. They also kept better following exposure to high temperatures than fruits or vegetables. The bacteria present in the meats, haddock, and salmon were mainly Gram-positive cocci, fluorescens types, achromobacter and flavobacter of several types. The flora was entirely different from that found on vegetables. The absence of anaerobes is notable.

presumptive tests for *B. coli* were negative, though closely allied species were present.

These data indicate that if good quality raw products are used freezing will preserve the food perfectly for a long time.

That the original bacterial content of fresh fish and probably of other foods is greatly reduced by freezing, has been shown by Birdseye,<sup>1</sup> Pease,<sup>2</sup> and Green.<sup>3</sup> Aside from the few results published by Birdseye,<sup>1</sup> no report was found bearing on the multiplication of microorganisms in frozen foods after thawing. Researches should be conducted on this important point. It is important that we know how long the various frozen foods can be kept at various temperatures before becoming unsafe or unfit to eat.

### SUMMARY

Frozen food factories are clean and modern methods of sanitation are used in preparing the many perishables now packed. The quality of the raw product is high and if the freezing is prompt and rapid, and the storage kept at low, constant temperatures, little or no deterioration in quality, appearance or nutritive value occurs. Several types of very efficient mechanical equipment are available to carry out the freezing process.

Fish, meats, poultry, eggs, and oysters are especially well preserved by freezing because they retain more nearly their fresh appearance, flavor, and character than fruits or vegetables. Most fruits are best when frozen with sugar and in this form retain their flavor very well. Vegetables are the most recent addition to the list of frozen foods. Though some varieties freeze very well, others do not. Both fruits and vegetables bleed freely on thawing. Spoilage occurs very quickly in vegetables after defrosting. More research is urgently required on the microbiology of frozen flesh foods and vegetables.

Little change occurs in the chemical, enzymic, or nutritive properties as a result of freezing. The changes are largely physical. Freezing greatly reduces the number of microorganisms present in foods, and prevents their multiplication. Emphasis must be placed on the prompt utilization of frozen foods. Until more is known about the subject, frozen products should be consumed while still frozen or within a very few hours after defrosting.

The ready availability of a large variety of frozen foods at all seasons will serve to give variety and balance to the human diet and should aid in decreasing nutritional deficiency diseases. The future of the industry is bright.

## Air Ambulances in Siam

A NOVEL feature of the health work in Siam is the air-ambulance service. Owing to lack of highways, the usual means of transport is the bullock cart. As this method is too slow for patients requiring urgent medical treatment, the government has arranged that the regular mail-service airplanes shall also carry sick persons, physicians, and medical supplies. Persons unable to pay are carried free of charge; for others there is a fixed mileage rate. Medical supplies for combating epidemics are transported free.

Siam now has nine Red Cross health centers, three of which are in Bangkok, where the first center was opened in 1923, according to the London *Mother and Child*. This Far-Eastern country, whose progressive absolute ruler recently visited the United States, also has a school, opened in 1925, which offers a 6-month course in public health nursing and midwifery to graduate nurses.—U. S. Children's Bureau, Washington, D. C.

# A Statistical Study in Maternal Mortality\*

E. S. MACPHAIL, F. A. P. H. A.

*Chief, Division of Census and Vital Statistics, Dominion Bureau of Statistics,  
Ottawa, Canada*

IT is a truism that the underlying object in compiling vital statistics should be as an aid in the protection and permanency of the community. They are not compiled merely to satisfy idle curiosity or to bolster some pet theory. Vital statistics, like all statistics, are not worth the time and money spent on them if the usefulness of the facts disclosed does not serve the State.

In the preparation of the material for the present paper a somewhat new line of approach to the important subject of maternal mortality was followed, namely, to treat it from a more or less purely statistical viewpoint. In looking over the reports of Annual Meetings of this Association within the last few years we find nearly a score of papers dealing with various phases of this subject, but nearly all were given before the Child Hygiene Section and we have no quarrel with the manner or place of presentation. It may further be remarked that in no instance did these papers deal with the purely statistical aspects of the subject.

In an endeavor to approach the subject from an angle which had not been so thoroughly explored it was thought that interesting and illuminating statistical results might be got by relating the maternal death certificates with the birth certificates corresponding to the event which terminated fatally for the mother, and when the record was dubious or insufficient by making supplementary inquiries to ascertain whether a birth had taken place. The reason that a reference had to be made to the birth certificates was that the mortality certificate did not show whether the death was associated with a birth or not. Therefore not having the necessary information to classify the death according to the kind of birth on the mortality certificate it became necessary to consult the birth certificate to ascertain whether the maternal death was associated with a live birth, a stillbirth or no birth. This investigation yielded some interesting discoveries, not the least of which was that of 70 deaths credited to "abortion," 13 of them were found to have been associated with a live birth and 7 with a stillbirth. The ex-

---

\* Read before the Vital Statistics Section of the American Public Health Association at the Sixtieth Annual Meeting at Montreal, Canada, September 17, 1931.

planation of these apparently contradictory assignments may be found in the too wide use of the term "abortion" as a cause of death by the physicians certifying. In each case the medical certificate gave the cause of death as "abortion," while our later search for the special purposes of this paper revealed the existence of a certificate for a live birth or a stillbirth.

Although the task promised to be tedious, yet, because of the interest presently evinced in maternal mortality and its associated phenomena, it appeared well worth the trouble to link wherever possible the maternal death with the birth certificate referring to the same event. The investigation was started first with the certificates for 1926, but the figures for that year being less detailed and less carefully investigated have not been used in this paper. For 1927 and 1928 the investigation was conducted in as thoroughgoing a fashion as the data available and the circumstances would permit, and it is with the results for these two years combined that this study deals.

It may be well to define some of the terms used.

1. *Birth*—The minimum period of gestation for which we knowingly accept a birth certificate in our statistics has been 6 months.

2. *Live Birth*—The criterion of a live birth has been respiration after complete birth, that is, after the complete extrusion of the fetus from the body of the mother.

3. *Stillbirth*—The child which has not breathed after complete birth is classed as stillborn.

4. *No Birth*—This term, as used in the tables herewith, includes cases of "abortion," "ectopic gestation," etc., and also those in which the woman was not delivered.

With regard to the definitions given of a "birth" and a "live birth," we apply the foregoing rules whenever the certificate contains the information which allows their use, though in many cases we have nothing to go on except the mere fact of registration as a "live birth" or "stillbirth."

Throughout this paper rates are computed on several different bases according to the purpose in view. For example, the rates for all puerperal deaths, regardless of their association with a birth or otherwise, are computed in the usual manner by their proportion to live births. Rates will also be found for maternal deaths associated with live births and stillbirths separately or with both combined, computed in each case on the number of live births or stillbirths or the aggregate of both as the case may be. In general, births are taken instead of confinements, the consequent difference in the rate being insignificant. In the comparison of deaths associated with single and multiple births, however, the rates are based on confinements. It is evident that no rate can be computed separately for those deaths not associated with

a birth, as we have not, and can probably never hope to have, a figure for the total number of pregnancies.

It will also be recognized that the results of an investigation of this sort, covering a country as extensive as Canada, with such varied conditions, climatic, economic, and social, and with a population comprising several racial stocks, is apt to contain biases due to unknown facts which may affect the classifications as well as the results. To take one example, as shown in Tables XII and XIII, the women reported with the 4th, 5th or 6th birth between the ages 25 and 30 are not likely to be representative of the various racial groups in the same proportion as those reported with their first birth at this age.

Table I shows that of the total of 1,300 deaths from puerperal causes in 1927, 642, or 49 per cent, were associated with a live birth, 256, or 20 per cent, with a stillbirth and 402, or 31 per cent, were not associated with either a live birth or a stillbirth. In 1928 the total number of deaths was 1,331 of which 636, or 48 per cent, were assigned to a live birth, 254, or 19 per cent, to a stillbirth, while the remaining deaths, reported as not being associated with a birth, numbered 441, or 33 per cent of the total. For the aggregate of the 2 years the deaths associated with a live birth were 49 per cent of the total, and with a stillbirth 19 per cent, while 32 per cent were associated with "no birth" as previously defined.

The death rate, calculated in the usual manner from the proportion of maternal deaths to the number of live births, was 5.6 in each of the years 1927 and 1928. If only those deaths associated with either a live birth or a stillbirth are considered, their proportion to the number of live births and stillbirths combined was 3.7 per 1,000 in 1927 and

3.6 in 1928. If on the other hand the deaths associated with live births are taken in proportion to the number of live births, and those associated with stillbirths in proportion to the number of stillbirths, the difference is very striking. Deaths associated with live births gave a rate of 2.7 per 1,000 for both 1927 and 1928, while those associated with stillbirths a rate of 35 per 1,000 in 1927 and 33.5 in 1928. This comparison of the rates for deaths associated with a live birth and of those associated with a stillbirth illustrates the recognized fact that in combating the prenatal conditions which result in a maternal death we are at the same time assisting in effecting a reduction in the number of children born dead.

In Table II the aggregate maternal mortality of each province for 1927 and 1928 combined is similarly presented under the same 3 divisions: Deaths associated with a live birth; deaths associated with a stillbirth; those cases in which "*no birth*" took place.

A discussion of the results of such an investigation by provinces would be too detailed for the purposes of this paper; furthermore the figures for the smaller provinces, particularly for Prince Edward Island, are not sufficiently large to give reliable results. It is noted, however, that the proportion of puerperal deaths not associated with a birth

TABLE III

DEATHS FROM SPECIFIED PUERPERAL CAUSES ASSOCIATED WITH LIVE BIRTH, STILLBIRTH OR NO BIRTH, CANADA, 1927 AND 1928 (COMBINED)

varied from 24 per cent in New Brunswick to 42 per cent in British Columbia.

In every province the rate for deaths associated with stillbirths is much higher than for those associated with live births, ranging generally from 10 to 15 times as high, when the rate for each of the 2 classes is computed on its appropriate denominator.

Table III gives the deaths associated with a live birth, a stillbirth, or no birth, classified according to the cause of death; and Table IV shows the proportional distribution of the deaths from each cause among these 3 categories.

TABLE IV

PROPORTION OF DEATHS FROM SPECIFIED PUERPERAL CAUSES WHICH WAS ASSOCIATED WITH LIVE BIRTH, STILLBIRTH OR NO BIRTH, CANADA, 1927 AND 1928 (COMBINED)

Int. List No.	Cause of death	Total	Associated with		
			Live birth	Still- birth	No birth
	All puerperal causes	1,000	486	194	320
143...	Accidents of pregnancy	1,000	98	64	837
144...	Puerperal hemorrhage	1,000	492	379	129
145...	Other accidents of labor	1,000	429	262	309
146...	Puerperal septicemia	1,000	582	99	319
147...	Puerperal phlegmasia alba dolens, puerperal embolism, sudden death in puerperium	1,000	684	140	175
148...	Puerperal albuminuria and convulsions	1,000	408	250	342
149...	Following childbirth (not otherwise defined)	1,000	711	186	103
150...	Puerperal diseases of the breast	1,000	1,000	—	—

Table IV exhibits for certain causes interesting variations in the proportion of deaths associated with a live birth, a stillbirth, or no birth. For instance, 49 per cent of the women who died from puerperal hemorrhage had a child born alive, while in 38 per cent the child was stillborn, and in 13 per cent there was no birth. For other accidents of labor the percentage of live births was 43, stillbirths 26, and no birth 31. The proportion of deaths from puerperal septicemia associated with a live birth was high, 58 per cent, while only 10 per cent were associated with a stillbirth; but deaths with no birth amounted to 32 per cent, evidence of the part which abortions play in swelling the total deaths from this cause. Deaths from phlegmasia alba dolens and embolism were associated with live births to a high degree, 68 per cent, while in only 17.5 per cent no birth took place. Where puerperal albuminuria and convulsions were the cause of death, live births were reported for 41 per cent, stillbirths 25 per cent, and no birth 34 per cent.

Table V gives the death rates per 10,000 births from each cause, column 1 covering all deaths and basing the rates on the proportion to live births after the usual manner; column 2 gives the proportion of deaths associated with live births to the total of live births and column 3 the deaths associated with stillbirths. It will be observed by a comparison of columns 2 and 3 that the proportion of the rate for deaths

1. Rate less than 1 per 10,000 live births

associated with stillbirths to that for deaths associated with live births is particularly heavy in connection with puerperal hemorrhage, other accidents of labor, and puerperal albuminuria and convulsions, and comparatively light for puerperal septicemia and phlegmasia alba dolens and embolism.

Table VI divides deaths according as they took place inside or outside an institution. The rates have been calculated for each cause based on 10,000 live births. Almost throughout the list of causes the institutional death rates are much higher than non-institutional. Such a comparison must be made with reservations, as in many instances hospitalization has taken place only when the outlook for a successful termination was doubtful. This appears to have happened in many cases where a death has been classified to "Accidents of Pregnancy," which investigation showed to have been incidental to an abortion *extra mural* in origin. Similar considerations apply to the rate for puerperal septicemia which for institutions was over 5 times as high as the non-institutional rate. Other causes also show an apparent bias against institutions.

To make a fairer comparison, Table VII takes in only those deaths which were associated with live births and compares the rates by causes as between institutional and non-institutional deaths. Even here it must be remembered that in many cases the woman may have been

brought to the institution owing to a serious condition following a birth outside. There is also a probability that the confinements in institutions included an undue proportion of cases in which some serious condition indicated the advisability of hospitalization.

The disparity between the rates for institutional and non-institutional deaths, while still existing in a fairly marked degree, has been greatly lessened by the inclusion only of deaths associated with live births. The rate for all causes combined, 3.5 times as great for institutions when all puerperal deaths were considered, is only 2.8 times as great when the comparison is limited to deaths associated with live births. In deaths from "Other Accidents of Labor," in which the proportion was 5 to 1 in the former case, it is only 3 to 1 in the latter. For puerperal septicemia it has been reduced from more than 5 to 1 to less than 4 to 1.

In Table VIII a digression has been made to illustrate hospitalization in relation to occupation of father. In comparing institutional with non-institutional rates it should be remembered that women whose confinement occurs in institutions are not proportionately representative of all classes in the community. A tabulation of institutional and

non-institutional births for certain typical occupations of the father, made for the year 1929, illustrates this point (Table VIII). It may be assumed that the years 1927 and 1928 would show similar differences between the various occupations in regard to the proportion of births occurring in institutions. A very small proportion of the children of fishermen, farmers and laborers were born in institutions. On the other hand, the proportion was high for professional workers, salesmen in stores, office employees, and owners and managers, these ranking in the order named. The births for which the occupation of the father was not given were nearly all to unmarried mothers. The proportion of these occurring in institutions was high.

Table VIII should not be accepted as furnishing conclusive evidence on hospitalization, but will accomplish a useful purpose if it stimulates further investigation.

In Table IX the puerperal deaths associated with live births or stillbirths have been classified by causes and by the time elapsing between the birth and the mother's death. Table X gives the corre-

sponding per cent distribution by elapsed periods. In all some 31 per cent of the deaths occurred within 24 hours after delivery. The percentage should be somewhat higher, as in those cases where the mother's death took place the day after the birth and no information as to the number of hours was available, it was assumed that 1 day had elapsed. Sixty per cent of the deaths occurred within 1 week, roughly 20 per cent in the 2d week, and the remainder were scattered over longer periods with less than 1 per cent taking place more than 3 months after the birth.

Of the deaths from puerperal hemorrhage, 72 per cent occurred on the 1st day, while only 4 per cent due to puerperal septicemia took place within this period, and 11 per cent more than a month after the birth. Deaths from puerperal albuminuria and convulsions occurred on the 1st day in some 37 per cent of the cases and within 1 week in 79 per cent.

Table XI classifies the puerperal deaths of married mothers which were associated with a live birth or a stillbirth according to the order of the birth in conjunction with the age of the mother. A presentation of Birth Statistics in the Canadian Annual Reports, from which the required figures for the age of mother and order of birth of the child have been extracted to form Table XII, has made it possible to present the rates for each category in Table XIII. The rates for very young mothers for higher orders of birth and those for mothers near the upper limit of the childbearing ages for lower orders are naturally based on a comparatively small number of births, and may be con-

sidered as not forming a typical cross-section of the married women of these ages. Rates which for these reasons were considered unreliable have therefore been omitted, and others which, although included, are based on fewer than 2,000 births are indicated by a footnote.

The lowest mortality rates for all orders of birth combined are for mothers between the 20th and 30th birthdays, with 2.8 maternal deaths per 1,000 births. Mothers under 20 show somewhat higher rates, and

TABLE XIII

1. Rates not computed on account of smallness of numbers involved
2. Rates based on fewer than 2,000 births

each 5-year age group above 30 shows an increase as compared with the group below it until a rate of 8.9 per 1,000 is reached for mothers 45 and over.

For primiparae the lowest rate is 3.0 per 1,000 for mothers under 20. The rates for 1st births mount with each increase in age until a figure of 22 per 1,000 is reached for women between the 40th and 45th birthdays. This last rate is based on fewer than 2,000 births.

For the 2d and 3d child, women between the 20th and 25th birthdays have the lowest rates, 2.1 and 1.7 per 1,000 respectively. For the 2d child the rate for mothers under 20 is the same as for those between the 25th and 30th birthdays. For both of these orders of birth the rates show a general tendency to increase with the advancing age of the mother, but the proportion of the rates near the upper limit of childbearing ages to the minimum rate is in each case less than for primiparae.

For the 4th, 5th and 6th children taken together, the lowest rate is found for mothers between the 25th and 30th birthdays. For the 7th, 8th and 9th children taken together, the first significant rate is for women 25 to 29, and the rate increases progressively from this group with the advancing age of the mother. The same tendency is manifest in the rates for the 10th child or higher order, for which the first significant rate and the lowest of those computed is for women between the 30th and 35th birthdays.

When order of birth is considered for the separate age groups, the rate for primiparae is in every case where listed much higher than for the other orders which have significant figures. For women between 20 and 35 the general tendency appears to be the approach to a minimum rate for the 3d child; for women between 35 and 45 the minimum rate is for the 4th, 5th and 6th children.

The lowest rate in the table is for women between the 20th and 25th birthday bearing the 3d child—1.7 per 1,000 births, based on 18,553 births.

To compare the risk in single and multiple confinements, the rate of maternal mortality has been computed for each of these classes with results as follows:

RATES FOR SINGLE AND MULTIPLE CONFINEMENTS

	Confinements	Deaths	Rate per 1,000
Single.....	473,832	1,719	3.6
Multiple.....	5,977	69	11.5
Total.....	479,809	1,788	3.7

Rate for multiple confinements is more than 3 times that for single.

Of the 1,789 deaths associated with live births or stillbirths, 884 were associated with male births, single or multiple, 792 with female births, 20 with twins or triplets of both sexes, and 93 sex not known. Taking only the 884 deaths associated with male births and the 792 associated with female births, and using male and female births respectively as denominator, we obtained rates of 3.5 and 3.4 per 1,000 respectively. Treating the deaths associated with live births separately, we obtained a rate of 2.4 with male births and 2.6 with female births. On the other hand, the deaths associated with stillbirths show a higher rate with male births than with female, the figures being 35.5 and 29.9 respectively.

In Table XIV, puerperal deaths have been listed according to the racial origin of the decedent and a rate for each origin calculated per 1,000 live births; also for deaths from puerperal septicemia. The deaths have been divided according to whether they were associated with a live birth, a stillbirth or no birth, and a percentage distribution based on these figures. Of the chief racial origins, the Scottish have a

Not specified	4	1.4	—	—	2	0.7	1	1	50.0	25.0	25.0

death rate of 6.6 per 1,000 live births, Irish 6.3, English 6.1, and French 4.9, compared with the general death rate from puerperal causes of 5.6 per 1,000.

The highest death rate is for mothers of Indian origin, amounting to 11 per 1,000, though this rate is probably affected by the more incomplete registration of Indian births. Other high rates are for women of Russian and Austrian origin, while Ukrainians give 4.9 per 1,000, well below the average. The term "Austrian" is somewhat ambiguously used, and usually refers to Slavic people from the former Austro-Hungarian Empire or their descendants. There seems no particular reason why this description should be favored more on death than on birth certificates, but it might be safer to consider the rate for decedents of Russian, Austrian, and Ukrainian origins as one total. The rate thus calculated is 6.3 per 1,000.

Women of Jewish origin show the lowest death rate, 3.2 per 1,000, and are closely followed by Italian women with a rate of 3.9 per 1,000, each based on approximately 5,000 births. Both Jewish and Italian women show a very low death rate from puerperal septicemia. Only 37 per cent of the deaths of Italian women were not associated with a birth, as compared with 46 per cent for those of Jewish origin, a high figure for the latter when considered with their low death rate and particularly with the low rate from puerperal septicemia. The number of deaths is small, and for this reason the interpretation doubtful.

In spite of the high death rate of Indian women, only 17 per cent of the deaths were not associated with a birth.

In addition to the deaths which were assigned to puerperal causes, there were in the 2 years 439 deaths assigned to other causes, but for which the medical certificates or replies to inquiries made mention of a recent pregnancy or parturition. These 439 deaths would give a rate of 0.9 per 1,000 live births, and added to the 2,631 deaths directly attributed to puerperal causes, would make a total of 3,070 deaths of women associated with pregnancy or childbirth, a rate of 6.5 per 1,000 live births. Of these 222, or 51 per cent, were associated with a live birth, 63, or 14 per cent, with a stillbirth, and 154, or 35 per cent, no birth. The proportion of these deaths not associated with a birth, and that with a live birth, were slightly higher than in the case of deaths attributed directly to puerperal causes, while a considerably smaller percentage of them was associated with a stillbirth.

Among the 439 deaths were 14 resulting from criminal abortion. These are classified as homicides.

# The Montreal Water Supply\*

C. J. DESBAILLETS

*Chief Engineer, Montreal Water Board, Montreal, Canada*

IN the year 1800, The Montreal Aqueduct was formed and received a 50-years franchise for the installation of a gravity system situated near Côte-des-Neiges, consisting of a wooden cistern with spring water fed by a wooden pipe. Today Montreal has 1,250,000 inhabitants and the St. Lawrence River provides its water supply.

What has happened during this 131 years would be too long to enumerate, but it is interesting to note the successive additions, taking advantage of progress both in machinery, pipes, and aqueduct system in general. In 1920, Montreal, having approximately 1,000,000 population, was in possession of an aqueduct system, taking its water from the St. Lawrence River through a canal 7 miles long, and had for the main pumping station a steam plant composed of various units of different sizes and makes. This station required approximately 80 men to operate it.

An event at the end of 1919 precipitated a radical change, and today the whole water supply of Montreal is pumped through modern electrically driven pumping stations of various stages. The event referred to was a general strike of the employees of the Montreal Aqueduct, which took place on New Year's eve, 1919, when the temperature was 20 to 25° below zero F. The strike lasted approximately 3 days, and Montreal was only saved from calamity by the sporting spirit of the citizens of all classes and ranks who volunteered to operate the steam plants, thus, under terrific handicap, keeping the water supply uninterrupted.

Soon after this the Montreal Water Board was formed, with recommendation to establish for the city a modern aqueduct system which could be operated safely and efficiently with a minimum of men, so avoiding a repetition of the trouble experienced in the winter of 1919. It is this system that I will briefly describe.

As stated previously, the St. Lawrence River is the source of supply for this aqueduct, and through the gates of Lasalle Bridge, the water is

\* Read before the Public Health Engineering Section of the American Public Health Association at the Sixtieth Annual Meeting at Montreal, Canada, September 17, 1931.

delivered to the filtration plant by a canal approximately 7 miles long, 200 ft. wide, and 20 ft. deep. The reason for this large canal is that ultimately the city will develop power from it which will be used for various purposes by the municipal authorities.

A filtration plant is located on the south side of the canal on land belonging to the city, and in the territory of the municipality of Verdun. This plant consists of 3 batteries of rapid sand filters of 50 m.g.d. each, and 1 slow sand filter battery of the same capacity, so that it is possible to operate at a capacity of 200 m.g.d., though, at present, it is operated at the daily rate of approximately 125 m.g.d. The water is pumped by low lift pumps from the canal over the filter, as it was found more economical to do so, instead of depressing the filters to feed them by gravity through the canal and pump the wash water through the sewer system of the city.

A lateral conduit of 9 ft. diameter is also available and having its intake approximately 1,000 ft. from shore, is capable of delivering approximately 100 m.g.d. of St. Lawrence water proper, as the north shore of the St. Lawrence water adjacent to the canal carries more or less of a mixture of Ottawa and St. Lawrence water, which is different from the St. Lawrence water, strictly speaking. It has more color and less alkalinity, and would require ultimately treatment by coagulation. However, up to the present, and under the supervision of the Provincial Board of Health, it has not been found necessary to coagulate the water of the Montreal Aqueduct, but the problem has been studied and plans have been prepared for coagulation basins, alum mixing plant, etc., so that when the quality of water supply may be judged by the Board of Health to warrant such a measure, the structures, basins, etc., can be built to be operated in conjunction with the present filtration plant.

Up to the present, owing to the excellent nature of the river water, we are only filtering the water supply through the rapid sand filters and after chlorinating the filtered water, it is found to be safe and absolutely suitable for domestic purposes. It is seen, that under the present methods, with the cost of coagulation eliminated, the Montreal water supply is treated at very reasonable expense, and this aqueduct is one of the most economical to operate on this continent.

Leaving the filter, the water is stored in a 26 m.g. underground reservoir, located between the filtration plant and the pumping station. This reservoir acts as a stabilizer between the constant output of the low level pumping units and the intermittent and irregular flow of the filter plant. It is equipped with a structure called the depressed bay, by which the complete reservoir may be put out of service for repair or

disinfection, and the water supply restored to the low level pumps by means of the emergency conduit tapped directly into the canal, and through which chlorinated water can be obtained to feed all the pumps of the low level pumping station during the time the reservoir or filtration plant is out of commission.

Special features of this conduit in regard to baffle plants, separation, etc., allow perfect feed of each individual pump, as well as the possibility, even under ordinary operation, of access to the suction of each pump separately.

#### LOW LEVEL PUMPING STATION

Owing to the various elevations upon which Montreal is built, it has been found necessary to divide the city into three zones, namely, the low level, the high level, and the high pressure zone.

The low level district or zone is supplied through the low level pumping station, which pumps directly into the mains of this low level zone, and to the McTavish reservoir which acts upon the low level system as an accumulator in which the difference of the water between consumption and the pumpage is stored. This reservoir has a capacity of 48 m.g. and is located on the side of the mountain.

The low level pumping station, which pumps the total supply of water, consists of a building in which electrical equipment is installed to control and operate six 30 m.g.d. pumps, driven by electrical motors; the ultimate capacity of the station is twelve such pumps.

The Montreal Water Board is actually finishing plans and specifications for the enlargement of this station where three 30 m.g.d. pumps will be installed, bringing up the total of pumps to nine. This station is operated by electricity. The electrical energy is delivered by two transmission lines and a third stand-by line, all being connected to a high tension loop of a power company having 4 to 5 large hydro-electrical plants located in various parts of the province and connected to different sections of this loop. The capacity of such a loop is more than 250,000 kilowatts.

Owing to the disposition described, the low level pumping station has been in operation for over 10 years, and it has never been found necessary to utilize the steam turbo-generator plant at its disposal through the power contract between the city and the power company.

The transmission lines are subdivided at the entrance of the plant in six 3-phase cables, two of which are suitable for the total load. In every circuit breaker, bus-bars are installed in duplicate and all precautions have been taken for quick repair, to prevent careless starting of motors. With the centralized control equipment located on 2 bench

boards, 2 operators only are necessary to keep this main pumping station in operation. Special features of protection both electric and hydraulic have been included in the equipment and have made the operation of this station almost fool-proof.

#### DISTRIBUTION CONTROL BUILDING

The water pumped by the low level pumps is distributed by 3 headers of 72" diameter into a building called the distribution control. In this building six 48" mains are so interconnected that with 1 header alone in operation, all mains can be fed with water, and as all the valves controlling these mains, and transfer valves from one main to another, are located in this building and are electrically operated from the main bench board of the station, the transfer of water distribution which may be necessitated by break or accidents in town can be taken care of by the operator on the hydraulic bench board of the low level pumping station.

Owing to the severe cold prevailing in the winter in Montreal, it has been found preferable to locate main valves in well protected, heated buildings in order to gain quick access to them instead of outdoors in chambers located at suitable points.

The six 48" mains deliver the water to the various parts of the city and, as stated above, some of these mains deliver water to the McTavish reservoir, which serves also as a suction well for the six pumps of the McTavish Pumping Station, which are repumping the water to the high level zone, having as a stabilizer the Côte-des-Neiges reservoir, as well as the Peel Street reservoir, to act on the distribution mains of the high level zone in order to take care of the difference of water between the consumption and the pumpage at McTavish Pumping Station. This McTavish Pumping Station also repumps the water into the Outremont reservoir and Outremont district in the same manner as it pumps water in the Côte-des-Neiges reservoir.

As an additional explanation we must say that recently the City of Montreal has purchased the Montreal Water & Power company which operated an aqueduct system similar to, but smaller in size than the one of the city, and in order to limit the pumpage for the two aqueducts to the low level pumping station and McTavish Pumping Station, it was necessary to redesign somewhat the main piping of the Montreal Water and Power Company, in order to convey the water to its former reservoirs, namely, Côte-des-Neiges and Outremont, by means of the McTavish reservoir and the new McTavish Pumping Station which take care of these services. Previously, the Peel Street reservoir was the only one acting upon the city high level zone, but now through

new connections the Côte-des-Neiges reservoir will take the place of the Peel Street reservoir, adding storage capacity to the system as well as increasing its pressure by approximately 20 lbs.

#### MCTAVISH PUMPING STATION

The McTavish Pumping Station has been recently constructed and is just being put in operation. It consists of three 12 m.g.d. pumps repumping water from the McTavish reservoir into the Côte-des-Neiges reservoir and three 15 m.g. pumping units repumping water from the McTavish reservoir into the Outremont reservoir. These six pumps are located in one room. They have been designed in such a way as to be all interchangeable, as regards to bearings, shafts, and bed plates, but not impellers because of the different characteristics of the service, or of the different curvature and width. Each of these two classes of pumps can be increased by changing the impeller from 12 million to 15 million for the Côte-des-Neiges service and from 15 to 18 million for the Outremont service.

This station is operated by means of two 3-phase cables installed between it and the Atwater Street station of the power company and connected to the high-tension loop referred to above, one cable being sufficient for the load, the other being kept as a reserve.

Besides these two cables, another source of supply through another cable is delivering energy at the McTavish from Vallée Street substation of the power company. With these three sources of power supply, the service of this station is expected to be as good as that of the low level pumping station. The electrical equipment is laid out in duplicate for oil circuit breakers, bus-bars, and affords a possibility of quick repair. The motors operating the six pumps are six 1,000 h.p. synchronous type, and capable of power factor correction up to 80 per cent leading power factor. The starting of these motors is done automatically and in case of interruption, we expect that this station operating two different services will be put back in service in the minimum time and without line disturbances.

#### HIGH PRESSURE ZONE

The high pressure zone is served by electrically driven pumping stations, one located at the Côte-des-Neiges reservoir which repumps the water of this reservoir into the system, having a small reservoir on top of the Westmount mountain to take care of the difference in the water between the consumption and the pumpage.

Another electrically driven pumping station located on Cedar Avenue pumps the water into its system, having a small reservoir on the

Montreal mountain to take care of the difference between the consumption and the pumpage.

The Montreal Water Board is now making plans and specifications for a similar pumping station and reservoir system to be installed in connection with the Outremont reservoir and to feed the upper part of the second Montreal mountain back of the University of Montreal. These stations will be made automatic owing to their smaller size.

This is in general a description of the Montreal Water Supply system. In reference to the distribution mains, until now they consisted mostly of cast iron and steel pipes, but recently reinforced concrete pipes have been used for higher pressures in order to avoid the bursting of cast iron pipes, and the corrosion affecting steel pipes, and electrolysis in both cases.

The Montreal Water Board is now installing a 34" reinforced concrete main between the McTavish reservoir and the Côte-des-Neiges reservoir.

In reference to water hammer, this question, after being carefully studied, has been solved by the use of Johnson valves. These, sometimes called "needle valves," consist of a plunger acting in a cylindrical chamber, and by moving this plunger back and forth, the valve is either closed or open. The operation of these valves is hydraulic and also electrical. The control device is arranged in such a manner that under an interruption of power the valve closes three-quarters of its stroke in a few seconds and the remaining quarter in a time adjusted to be between 5 to 10 seconds, thus eliminating the water hammer. In other words, these valves act as slow closing check valves. We have in the low level pumping station 18 of these and in the McTavish Pumping Station 8. Similar valves will be installed in various parts of the city, so as to close automatically sections of the distribution system in case of a break or trouble.

#### CHLORINATION OF WATER

Our chemist and filtration plant superintendent have been working for many years on a chlorinating device of very different nature from the ones generally in use. This chlorinator is based on the faculty of a photo-electric cell to change its resistance in proportion to the light it receives.

## BOVINE TUBERCULOSIS AND HUMAN HEALTH

A REPORT of more than usual interest has recently appeared.<sup>1</sup> At the London Congress on Tuberculosis in 1901, Robert Koch lent his great authority to the belief that bovine tuberculosis did not constitute a menace to human health. While there were those at the Congress who combated his position, it was not until 1902<sup>2</sup> that positive proof, such as had been demanded by Koch, was given that the bovine organism could produce tuberculosis in human beings. Two National Commissions, one English and the other German, have since confirmed the fact that bovine tuberculosis is transmissible to human beings, and it is safe to say that there is no one in the world today who ranks as an authority who does not admit the fact, though there is still some question over the actual amount of human tuberculosis due to infection from bovine sources. Thirty years have passed since the positive proof was given. In the meantime, many private workers have given added testimony and it seems curious that there are still so many people who ignore or belittle the danger of cattle to human beings as a source of tuberculosis.

The report in question states that while the incidence of bovine tuberculosis varies, in some places it is responsible for between 10 and 15 per cent of the cases of tuberculous bones and joints, and urges that this source of infection be more carefully guarded against. It states further that of children under 5 years of age suffering from tuberculo-

sis, 21 per cent of the cases are due to the bovine type of organism, while between the ages of 5 and 16 the percentage rises to 26.

It seems needless to add that pasteurization is at present our greatest safeguard, though the difficulties of having this process carried out properly in rural sections and in small towns are evident. Federal, state, and city governments have played a large and commendable part in bringing about as good conditions as now exist, but it is evident that much remains to be done.

An interesting observation quoted from Dr. Maxwell Harbin, of Western Reserve University, is that there has been a steady decrease in tuberculous disease of bones and joints in children, but an increase in adults. He attributes this as being probably due to the protection given by public health measures during childhood, and expresses the fear that due to the depression through which the country is now passing, public health activities may be let down and the situation be changed. His opinion is apparently shared by a number of other investigators in various parts of the country.

Certainly we have here a strong incentive for urging health authorities not to relax in any degree their efforts, and for appropriating bodies to maintain to the fullest possible extent their financial support.

### MENTAL HEALTH IN HARD TIMES

IN times like the present there is much talk about widespread mental and nervous disturbances, due to the stresses and strains induced by economic distress. It is natural to assume that conditions such as those created by the current depression, which is so severely taxing the adaptive capacities of a large section of the population, would tend to unbalance many of the more poorly adjusted and result in a higher frequency of mental and nervous disorders.

It is true that the depression is adversely affecting the mental and emotional lives of a great many of us and is causing all sorts of maladjustments in individual, family, and social life, especially among those whom the depression has hit the hardest—the unemployed. There is ample evidence to this effect. There is no evidence that it is greatly increasing admissions to mental hospitals, and there is little ground for alarming statements, such as have recently appeared in the press, that point to a tremendous rise in insanity, crime and suicide “all the outcome of nervous disorders induced by present-day condi-

tions." There is little in the way of first-hand information, based on impartial, objective study, to warrant such a generalization.

A preliminary inquiry by The National Committee for Mental Hygiene reveals no country-wide rise in mental disease of institutional severity, although here and there mental hospitals do report increases in admissions and readmissions. It is not likely that conditions would reflect themselves so soon in this way. Mental diseases do not occur suddenly, but develop gradually over varying periods of time, and the factors that enter into the production of mental diseases are too numerous to look for a mass increase in mental diseases from any one cause, or even one set of circumstances, like those of the present economic emergency.

As a matter of fact, we are not so sure that mental diseases have increased to any great extent, if at all, in recent years. There is a strong presumption that they have, but there is no conclusive evidence, one way or the other. The number of mental patients under care, it is true, has increased and multiplied, but authoritative opinion on the whole has referred this to the widespread increase in the provision of treatment facilities coincident with the advent of mental hygiene, not to an equivalent increase in mental disorders. More mental illness has been uncovered, thanks to the educational effects of the mental hygiene movement. The inimical effects upon mental health of the high-powered living conditions of the modern era have been assumed but not proved.

There is no recorded jump in hospital admissions consequent upon the World War, another capital crisis that might have been expected to land great numbers of us in mental institutions. Nor are there indications as yet that lead us to expect any wholesale increase in admissions to mental hospitals in the immediate or remote future as a result of the depression. Even if there should be a marked increase, it will be difficult to isolate the economic factor as a major determining cause. The problem of mental disease is too complex; there are too many unknown factors. It is said that there have been many more suicides since the depression. In this respect the findings in mental hospitals are negative.

While we may not be heading for an epidemic of mental disorders of such proportions as to swamp our hospitals with mental cases, it is evident, nevertheless, that the depression is creating serious mental problems. There is, for example, a decided increase in admissions and readmissions to institutions for the feeble-minded, indicating a marked tendency to eliminate the lower grades of the mentally defective from industrial and social life. As there are institutional facili-

ties for only a fraction of the number of mental defectives in the community, enforced idleness in this group may well be complicating the problem of crime, delinquency, and dependency.

Nearly all state institutions report a reduction in their discharges and paroles, another result of unemployment conditions, which is making it difficult to return patients to the community. It is here that the depression will have one of its worst effects. Added to the chronic overcrowding of mental hospitals and the lack of adequate facilities and personnel for individualized attention, this swelling of institutional populations will make it all the more difficult to maintain standards of care and treatment above the custodial level. There is little money available for institutional expansion. Many curable cases will become incurable, due to the curtailment of treatment facilities.

Preventive work is being retarded, by the restriction of clinical and other mental hygiene activities. There is a temptation to provide only for the immediate necessities, and to cut down on provisions for active treatment and forward-looking preventive measures. The depression is accentuating problems in human adjustment which make mental hygiene work all the more necessary, yet budgets are being drastically reduced.

These problems are reacting on the younger generation in many ways. Marked changes in family life have been noted. Among the destructive effects of economic distress are, for example, those observed in children who develop extreme anxiety because of lowered morale in the home and the fear as to what may happen to that home. This, in turn, engenders hostility toward society, which is blamed for allowing such a situation to occur. The depression is undoubtedly undermining individual and family security; and a sense of security, psychological and economic, is essential to the maintenance of good mental health. The experience of our mental hygiene clinics may have something to show in this connection in the next year or two.

Child guidance workers report that offenses against property have increased during the past two years, and that conditions are favorable to a rise in the number of youthful offenders. Adolescents who in normal times would be working out their problems in healthful emancipation are now balked in making the normal adjustments, because of their difficulty in finding work, and psychologically speaking, their place in life. They are developing habits of idleness and other personality traits that augur ill for later life.

Thus we see many by-products of the depression that are aggravating the mental health problem in various ways. The mental hospital is not the only barometer of the effects of the depression on mental

health. We expect to see not so much a large increase in hospital cases of mental disease as in the incidence of the milder mental and nervous conditions, of personality disorders and maladjustments of various kinds and degrees, not only among the underprivileged but in all classes of the population.

### THE SIXTY-FIRST ANNUAL MEETING

THE Sixty-first Annual Meeting of the American Public Health Association will be held in Washington, D. C., October 24-27, 1932. The headquarters will be the Hotel Willard.

The scientific excellence of Annual Meeting programs is too well known to need further comment. The annual gathering of public health workers which the American Public Health Association sponsors has achieved such a reputation that allied organizations in increasing numbers are planning meetings at the same time and place. This year we shall welcome to our sessions members of the following organizations: American Association of School Physicians, American Social Hygiene Association, International Society of Medical Health Officers, Conference of State Sanitary Engineers, Conference of State Laboratory Directors, Association of Women in Public Health, Oyster Growers and Dealers of North America, and National Shell Fisheries Association.

The American Association of School Physicians as a body will join with our Child Hygiene and Public Health Nursing Sections for one or more discussions. In order to avoid conflict with the many fine things they know by experience will be scheduled by the American Public Health Association, the School Physicians will hold their individual meetings on the Friday, Saturday, and Sunday before October 24. The Conference of State Sanitary Engineers will meet as usual on Friday, Saturday, and Monday and then merge their meeting with the Public Health Engineering Section.

The Public Health Education Section is undertaking for the first time a Health Education Institute, arranged for Saturday and Sunday, October 22 and 23. The students, limited to 25, will be drawn from the growing body of health education workers in official and nonofficial agencies. The instructors will be individuals who have had practical experience extending over many years in the creation and development of programs of health education in health departments and other health organizations. It is safe to say that such a faculty could not be assembled in any university in the United States. A short, intensive course in the philosophy and principles of health education will be

given, and students will be told how to build a program, how to set it up, and how to carry it through, with adequate instruction in the implements available for the projection of health information including the use of the spoken word, the printed word, the picture, the poster, and the motion picture.

The Industrial Hygiene Section will present an exhibit of major preoccupations of the Section. The results of experimental and research work will be shown, new methods found successful in the treatment and diagnosis of occupational diseases, and in general, progress and problems in preventive medicine in industry will be illustrated. Original work is demanded by the Scientific Exhibits Committee, and each exhibit will be in the name of the individual responsible for it.

This exhibit will be placed in one section of the Willard Room near the exhibits of services, products, and equipment, believed to be of value in health protection and promotion, which are provided by our commercial exhibitors every year. The Palm Room will also house commercial exhibits. A number of new products have been developed and marketed during the past year, which have not been called to the attention of members of the American Public Health Association up to this time. The health exhibit is always a feature of the Annual Meeting and of real service to the delegates.

Everyone knows that the ten sections of the Association hold individual meetings, and two or more combine frequently for joint meetings. Special sessions on timely subjects calculated to interest the majority of members are always arranged. The opening general session will take place on Monday evening with Dr. Dublin's Presidential address the main feature. The annual banquet will be held on Wednesday evening. A special session on mental hygiene and a presentation of the work of the ten Sections will be scheduled for two afternoons. A third session is being held open by the Program Committee to permit a discussion of topics which may be pertinent later in the year and which cannot be anticipated at this time.

The Section programs, still incomplete, show many interesting things. The Committee on Training and Personnel will sponsor a luncheon meeting at which the training of engineers, nurses, and health officers will be discussed. Diphtheria will be the topic at another luncheon meeting. Several sections are developing symposiums. There will be one on air hygiene; one on incidence, identification, and significance of bacterial carriers; one on Standard Methods; one on bacterial dissociation; one on vital statistics registration problems; and one on participation of the medical profession in health education.

The Washington Local Committee, under the able direction of Dr.

William C. Fowler, Chairman, is arranging a program of inspection trips in and around Washington, and of entertainment in which every delegate will be interested. A minimum amount of recreation is essential during a scientific meeting extending through four days, and the value of social contacts made at such times should not be overlooked.

Members of the Association will travel to and from Washington at the convention rate of three-quarters of the round trip fare granted by the railroads. Lower-than-usual rates for hotel accommodations have been secured for members by the Association. Attendance at the Sixty-first Annual Meeting need not be expensive. Perhaps more than at any time in recent years is an expenditure for travel to the Annual Meeting justified. Health workers who are fighting reduced appropriations in the face of increasing responsibilities will have their courage restored through the awareness of their numbers, their strength, and their influence that gathering together in Washington will impart.

# ASSOCIATION NEWS

*Sixty-first Annual Meeting of the A. P. H. A.  
Washington, D. C., October 24-27, 1932  
Headquarters, Willard Hotel*

## NEW MEMBERS

*The following list includes applicants who have been approved for membership in the A. P. H. A. by the Sub-committee on Eligibility. These new members have requested affiliation with the sections indicated, and action by the Section Council will follow.*

### *Health Officers Section*

Pedro Rivera Aponte, M.D., Public Health Unit, Cayay, P. R., Health Officer  
Dr. Manuel B. Berrios, M.D., P. O. Box 92, Yabucoa, P. R., Health Officer, Public Health Unit  
Francisco J. Casaldue, P. O. Box 935, Mayaguez, P. R., Director, Public Health Unit  
George E. Clarke, M.D., Oakland, Md., Deputy State Health Officer  
John R. Downes, M.D., Newark, Del., Deputy State Health Officer  
Dr. Percival E. Faed, Gainesboro, Tenn., Officer in charge Trachoma Control Activities  
Mario McC. Fischer, M.D., Health Dept., Duluth, Minn., Director of Public Health  
Carl M. Gambill, M.D., Salyersville, Ky., Health Officer, Magoffin County  
Andres Montalvo Guenard, M.D., Public Health Unit, Bayamon, P. R., Health Officer  
Guy G. Lunsford, M.D., Millen, Ga., Commissioner of Health, Jenkins County  
George F. Reeves, M.D., Nashoba Assoc. Boards of Health, Ayer, Mass., Health Officer  
Juan del Rio, M.D., Loiza, P. R., Chief, Public Health Unit  
Julio A. Santos, M.D., Box 746, Arecibo, P. R., Director, Public Health Unit  
Rafael Ramirez Santos, M.D., Salinas, P. R., Health Officer  
Raymond L. Smith, 518 S. Dickel St., Anaheim, Cal., Food and Sanitary Inspector  
Rafael S. Vazquez, M.D., Manati, P. R., Chief, Public Health Unit  
Charles G. Wharton, M.D., 116 Temple St., Los Angeles, Calif., Asst. City Health Officer

Cas. P. Wilson, M.D., Sevierville, Tenn., Box 54, Health Officer

### *Laboratory Section*

Vivian R. Lederer, Pomona Health Center, Pomona, Calif., Bacteriologist  
Rocco Leone, Waltham Inn, Waltham, Mass., Laboratory Technician  
Paul S. Nice, 312 17 St., Denver, Colo., Consulting Bacteriologist  
Nelly K. Whitfield, Box 18, Dotham, Ala., Director, Dotham Branch of State Laboratory

### *Public Health Engineering Section*

General T. Prater, Cleveland, Tenn., Sanitary Officer

### *Industrial Hygiene Section*

Thomas M. Carey, 622 Jefferson Ave., Defiance, O., Ventilation Engineer  
Daniel H. Goodnow, Jr., 6 Jackson Road, W. Medford, Mass., Student (Assoc.)

### *Food and Nutrition Section*

Donald H. Cook, Ph.D., School of Tropical Medicine, San Juan, P. R., Associate Professor of Chemistry and Nutrition  
Luis G. Hernandez, School of Tropical Medicine, San Juan, P. R., Instructor in Chemistry  
J. Edward Kimlel, 502 U. S. Custom House, Denver, Colo., Charge Food and Drug Admr., Lab.  
John S. Koen, Rm. 64, Municipal Courts Bldg., St. Louis, Mo., Chief Meat Inspector  
G. Edward Pendray, 450 W. 22 St., New York, N. Y., Editorial Dir., Milk Research Council (Assoc.)

Rafael del Valle Sarraga, P. O. Box 935, San Juan, P. R., Director, Chemical Laboratory

*Public Health Education Section*

Arthur H. Bryan, V.M.D., 4400 Raspe Ave., Baltimore, Md., Assistant Professor of Bacteriology, University of Maryland

Clough T. Burnett, M.D., 550 Metropolitan Bldg., Denver, Colo., Associate Professor of Medicine, University of Colorado

Caldwell Martin, 704 Symes Bldg., Denver, Colo., Member Executive Comm., Denver Community Chest (Assoc.)

Cornelia Mooter, 4809 Baring Ave., E. Chicago, Ind., Teacher, Physical Education, McKinley School

William H. Perkins, M.D., 1430 Tulane Ave., New Orleans, La., Professor and Director Dept. of Preventive Medicine

Ruth E. Whitney, Dept. of Public Health, Yale School of Medicine, New Haven, Conn., Assistant

*Public Health Nursing Section*

Douschka M. Alford, Elizabethton, Tenn., County Public Health Nurse

Marion G. Crowe, 303 Fitzpatrick Bldg., Portland, Ore., Supt., Visiting Nurse Assn.

Mary C. Ferguson, R.N., Liverpool, N. S., Victorian Order Nurse

Margaret Leddy, R.N., 3312 Federal St., Camden, N. J., Local Supervisor, Metropolitan Life Insurance Co.

Helen J. Marble, 204 High St., Pawtucket, R. I., Director of Nurses, Central Falls Chapter, A. R. C.

Cecilia M. Mink, R.N., 541 Washington St., Allentown, Pa. (Assoc.)

Essie M. Sanborn, County Health Dept., Trenton, Tenn., Public Health Nurse

Margaret Stiles, R.N., Box 54, Sevierville, Tenn., Public Health Nurse

*Unaffiliated*

Lester L. Griffith, Box 54, Sevierville, Tenn., Sanitary Inspector

George B. Holmes, Dresden, Tenn., Sanitary Inspector, Weakley County Health Dept.

DECEASED MEMBERS

George Eastman, Rochester, N. Y., Elected Honorary Fellow 1915

Carl C. Gibbs, Lake Forest, Ill., Elected Member 1928

Herman O. Hodson, Hillsboro, O., Elected Member 1930

E. Franc Morrill, M.D., Rock Island, Ill., Elected Member 1930

D. Palmer Smagg, M.D., Stottville, N. Y., Elected Member 1926

# PUBLIC HEALTH ADMINISTRATION

## ANNUAL REPORTS

JOHN P. KOEHLER, M. D., F. A. P. H. A.

*Health Commissioner, Milwaukee, Wis.*

ONE of the most annoying problems that every health officer has to face annually is the compiling of an annual report. It is an accepted fact that every well managed organization makes an annual report to its members or stock holders. A health department can be no exception, if it wishes to maintain the confidence and coöperation of its supporters.

The compiling of annual health department reports is becoming more and more of an onerous duty for the health officer, instead of a much desired opportunity. This is due to several reasons. While a great deal of emphasis is laid upon annual reports by health authorities, the importance of such reports is not always appreciated by those responsible for the health department's budget. The question, therefore, arises, how can a health officer issue a report which is a credit to his department without having any or adequate funds set up for such a purpose?

Not only does a health officer have to worry about the cost of his annual report, but also about its contents. If he makes a long detailed report, he is told that no one will take the time to look it over, and if he condenses his report too much, he is in danger of omitting information desired by other health departments and also necessary in his own office for future reference. Since 1921, the Milwaukee Health Department was not given any funds for the printing of an annual report. A condensed report of the Health Department activities has

been included in the annual report of all city activities by the Municipal Reference Library. This has been the only report available to the general public. For its own files and for the Mayor, the Common Council, and the Municipal Reference Library, the Health Department prepared four complete typewritten reports. This arrangement has not proved entirely satisfactory because the condensed report of the Library did not contain sufficient information for people especially interested in health work, and the typewritten reports were not available for public distribution.

It is for this reason that it was possible to persuade the Municipal Reference Library to give the Health Department more space in its annual report for 1931. Since it was considered extravagant to mail complete reports of all city activities to people who were only interested in the Health Department's work, it was decided to have reprints made of the Health Department's report. The Library paid for the reprints of a 40-page report at a cost of 5 cents each. The Health Department paid for 3 extra pages and a cover for the reprint at 7 cents each. This arrangement made it possible for the Health Department to have 400 copies of a printed report for general distribution at a cost of \$28.00, which could easily be spared from its general publication fund.

It has also been found advisable to make some changes on the typewritten report kept in the department for a

permanent record. In the past, we have depended a great deal upon our letter files for the keeping of valuable information. We have learned from experience, however, that it is very difficult to get information out of a letter file concerning events that occurred many years ago. It is for this reason that, beginning with the report of 1931, the typewritten report will not only contain a detailed account of the various activities of each division of the Health Department, but also an appendix containing all information which might be of value in future years.

Such an appendix might contain not only all ordinances passed, but also ordinances defeated, with the reasons for their defeat. All special surveys and reports which might be too cumbersome to insert in the regular report can be included in such an addition. Many discussions on controversial subjects occurring during the year might be entered in such a report and yet be out of place in a report leaving the Health Department. Copies of very important letters and other documents can be entered in such an appendix. At the present time it is almost impossible to obtain much detailed information on events that occurred 10, 15, or 20 years ago, because reports compiled and printed for the use of the general public can obviously not contain all of the information desired from time to time by the Health Officer and his associates.

Necessity has been the mother of invention in the Milwaukee Health Department. Where it was unable to have one report printed due to lack of funds, it is now preparing three reports; one condensed, printed report for general distribution, three complete typewritten reports for the Mayor, the Common Council, and the Municipal Reference Library; and one detailed typewritten report with supplementary material for the files of the Health Department.

In addition to these three reports, the

Health Department issues a statistical report for other health departments, and prints a summary of its annual report in 9,000 copies of its monthly bulletin.

Decatur, Ill.—With an estimated population for 1931 of 58,600, there were 1,133 births in Decatur, a rate of 19.3; 738 deaths, giving a rate of 12.6.

Especially noteworthy was the fact that there were no maternal deaths, which is an unusual record for a community of any size. Among the more important causes of death were heart disease, cancer, pneumonia, and apoplexy. Tuberculosis has been relegated to 7th place on the list and, with 21 deaths, was only slightly above suicide with 19 deaths. The infant mortality rate was 47.6. The Health Commissioner is to be congratulated upon a very readable type of report, illustrated with simple pictures. The material is presented in such manner as to be very useful in the Interchamber Health Conservation Contest.—*Annual Report*, City of Decatur, Ill., 1931.

Framingham, Mass.—This city had the lowest death rate of its history, 9.9 per 1,000, in 1931, and a new low figure for tuberculosis of 22.5 was established. With a population of 22,222, there was expended for public health work the sum of \$24,686.33 or \$1.11 per capita.—*Annual Report*, City of Framingham, Mass., 1931.

Evanston, Ill.—The net death rate figure, excluding non-residents and after correcting for the deaths of citizens of Evanston in Chicago, was 8.02, a slight decrease over 1931. Among the principal causes of death were: heart disease, cancer, cerebral hemorrhage, pneumonia, and tuberculosis. The infant mortality was 39.2, an advance over the rate of 33.8 for 1930. There were 4 more cases of diphtheria than in the preceding year, and 8 more carriers

were found. However, 9 cases including 1 carrier and 1 death occurred in a single house into which a family from the country had moved but a short time before the outbreak. All told, there were only 19 cases of diphtheria, 7 of which were in the preschool group.—*Annual Report, City of Evanston, Ill., 1931.*

Salem, Mass.—The death rate of 13.1 was slightly higher than that of the preceding year as was the infant mortality rate. There has been a noticeable decrease in diphtheria cases and deaths. With a population of 43,353, there were reported only 14 cases of pulmonary tuberculosis and 9 cases of other forms of tuberculosis. There were 10 cases of infantile paralysis, of which 2 were fatal.—*Annual Report, City of Salem, Mass., 1931.*

Child Hygiene in Pennsylvania—With the coöperation of the Department of Public Instruction, all new school building projects were referred to the School Division of the State Department of Health for investigation of the water supply and the proposed method of sewage disposal. A total of 555 investigations were made and finally approved as a result. Improvement of sanitary conditions in school buildings throughout the state was secured by personal conferences with the school boards and county superintendents of schools. Among other results, there were 228 school buildings equipped with flush toilets.

Two motor units spent 3 summer months as usual in rural districts. Each car operated with a staff of 2 doctors, 2 dental hygienists, and 2 or more nurses. The cars the past year for the first time were driven by medical students. A special feature of the summer was the attention given to vision testing of children of 4 years of age and over. The 2 medical students were instructed in

vision testing by the Director of Sight Conservation of the State Council for the Blind, and under her guidance each student was given experience preparatory to the motor unit work. There were 378 cases found of children having eye defects, and extra follow-up care was necessary in order to insure against further sight damage. In the areas visited, local committees were formed if there were not already Parent-Teacher Associations or other organizations to coöperate in the child hygiene work carried on by the motor units. All cases found with defects were referred to the family physicians, and home visits were made by nurses or lay committee members to aid in stimulating parents to secure necessary professional attention.—*Yearbook, Pennsylvania Dept. of Health, 1930.*

Cattaraugus County (N. Y.) Developments—The 9th year of the county health unit plan of Cattaraugus County is marked by the taking over of the routine services by public authorities, the beginning of a series of investigative projects, supported by the Milbank Memorial Fund, and progress in integration of health and welfare authorities, particularly enhanced by the gift of the Bartlett Community Center in Olean, in which are now located the offices of most of the health and welfare agencies of the county.

The budget for 1931 totalled \$87,000, half of which came from the county, and a like amount from state funds. The department has taken over responsibility for health in the Allegany Indian Reservation, hitherto covered by one nurse under the District State Health Officer. In addition, the county health officer serves as health officer to Allegany State Park, this arrangement having been approved by the State Park Commission and the Cattaraugus County Board of Health.

The birth rate seems practically

stationary, being 20.2 for 1931, as contrasted with 20.4, the average for the 10 years. The infant mortality rate for 1931 was 64, with a 10-year average of 72. The diphtheria situation has merited special attention. Fourteen of the 26 cases occurred in one town where 64 per cent of the preschool children are immunized. This suggests increased virulence of the diphtheria organism, and is considered a warning to other communities that diphtheria is still a dangerous disease. The tuberculosis death rate for the county for the past 10 years shows a remarkable decrease, from 68.3 in 1923 to 41.4 in 1930, and a new low level of 30.8 in 1931, 28 per cent less than the 5-year average. Evidence in the county points toward a low rate of infection under 20 years of age, and the bureau looks forward to establishing tuberculin testing and X-raying in the larger schools as its next step forward.

The nursing program aims to give the best possible service for the amount of money appropriated. Although the staff is large in comparison with that in many rural areas, it is about half the size actually desirable. The withdrawal of the state nurse from the Indian Reservation has added considerably to the existing case load of each nurse. This year for the first time a student program has been attempted.

Classes in home nursing, child care, and first aid, taught by nurses in 1931, reached 236 persons. In rural communities this aspect of the work is important. School work is shown to have occupied 11 per cent of the nurses' time and is on the increase. It is felt to be time well spent, and Cattaraugus County schools far exceed *Appraisal Form* standards in correction of defects. In the fall of 1931, a new school program was inaugurated with the following objectives: (1) Higher percentage of correction of defects; (2) more parents present at school physical examina-

tions; (3) better building inspection; (4) a more uniform health education program; and (5) improved record systems for teacher and nurse. All of these aims have been partially realized.

Since specialized supervision has been discontinued, staff education is being carried on by means of the available services of the State Department in the form of group conferences, institutes, and extension conferences.

The year 1931 represents the 3d year of operation of a sanitation bureau under the full-time supervision of a sanitary engineer. The report reviews the variety of service given and shows a demand for supervision of private water supplies, drainage problems, building sanitation, public water supplies, milk control, sewage disposal, and the like. A demand for sanitary sewage disposal systems for rural schools is noted.—*Cattaraugus County Dept. of Health Report, 1931.*

**Orange County, Calif.**—A full-time health unit was initiated in Orange County in 1923. Its jurisdiction was at first limited to the unincorporated area, but gradually service has been extended to towns and cities. A population of approximately 120,000 is now served. Newport Beach is the only city having its own health department.

School health work, with the exception of communicable disease control, is in some districts under the direction of the Board of Education. In others, it is under the direct supervision of the Health Department, but reimbursement is made by the Board of Education on the basis of service rendered. In the examination of 12,485 children, a total of 6,444 physical defects were found, and of these, 1,684 were corrected during the year.

Thirty-three child welfare clinics were held every month in various parts of the county. A registration of 7,046 infants and preschool children represents

an increase of 2,474 over 1930. No prenatal clinics are held. Expectant mothers coming to the attention of the health department are referred to the County hospital for this service.—*Annual Report*, Orange County Health Dept., Calif., 1931.

**Tuberculosis Mortality Among Young Women**—A very careful sociological study of the 180 deaths from tuberculosis among young girls from 15 to 25 years of age which occurred in Detroit in 1930 has been made. That the tuberculosis death rate among adolescent girls has been declining at a less rapid rate than has occurred for other age and sex groups is well known to all students of the subject.

The author concludes that up to the age of 18, no marked disparity was evident between the male and female tuberculosis rates. She recognizes that the problem of tuberculosis among the negro population is serious and appears to be accentuated among young females. The author further concludes that the income of the family had no particular influence upon the tuberculosis mortality, nor did the housing conditions under which these individuals lived.

Deaths were not concentrated among uneducated girls but occurred in a group which slightly exceeded the normal educational level. Employment of girls exerts little if any influence. There is no indication that the wearing of insufficient clothing was a contributory factor. The emotional tension and the ambition for popularity reflected in the forms of recreation enjoyed, together with insufficient rest, probably combined to predispose to tuberculosis in a considerable number of cases.

There was evidence of a distinct tendency toward marriage and child-bearing at an early age. Pregnancy during the age period before 20 was common and closely linked up with the onset of disease. Undoubtedly this

constituted the most important single causative factor in the mortality of this group.—Edna E. Nicholson, *A Study of Tuberculosis Mortality Among Young Women*, Social Research Series No. 1, National Tuberculosis Assn.

**New York State**—"Public health should be the State's paramount interest and the success or failure of any government must be measured by the well-being of its citizens," declared Governor Franklin D. Roosevelt, in commenting upon the final report of the Governor's Special Health Commission, entitled "Public Health in New York State," recently made public. After nearly 2 years of study, the commission, of which President Livingston Farrand of Cornell University is chairman, and State Health Commissioner Thomas Parran, Jr., is secretary, has submitted the final report.

Hailed by authorities as the most adequate survey ever made of the public health resources of the state and the most comprehensive state program for individual and community health action ever formulated, the report should attract wide interest among public authorities and community leaders throughout the United States. The new health program recommended by the commission sets up guideposts for long-range planning and action in public health for the next decade or two. Special attention is called to the unnecessary cost of preventable sickness and the savings in community expenditures for community relief which are possible by the application of modern methods of disease prevention. The report recommends that the present system of local health service be reorganized by substituting the county for the town and village as the local unit, with the appointment of a county board of health and health commissioner in all counties.

"Only half of the chapter on tu-

berculosis has been written," said the Governor. "During the past 25 years tuberculosis has been dislodged from 1st to 6th place as a cause of death, and its rate cut in half. Its rate may again be cut in half and the reduction in present expenditures for caring for the victims of this disease will pay the cost of the new health program." It is recommended that the three state tuberculosis sanatoriums which have been authorized be constructed and put in operation with the least possible delay. A more comprehensive tuberculosis control program is outlined.

The commission points out that of the 5,606 infants under 1 year of age who died in New York State in 1930, more than one-half would still be living if every community utilized the simple, well known measures which over and over again have proved effective in saving the lives of babies. Other than the indifference of local governments, there is no reason why twice as many babies should die each year in some counties and cities as in other communities where a modern health program is in force, or for tuberculosis to be twice as prevalent in some counties of New York State as in others. Deaths and illness from diphtheria continue to occur, whereas some municipalities have been able to stamp it out entirely. Among the important recommendations dealing with maternal and infant hygiene, it is suggested that the State Department of Health appoint a Maternity Commission to advise in respect to its maternity program, to revise and apply present standards of maternity care, to appraise the findings of case investigations, and to point out the methods of preventing maternal deaths.

The need for prompt and competent treatment of venereal diseases is stressed. The commission presents evidence that these diseases are among the most serious of our public health prob-

lems and that their control is possible by methods similar to those which have proved effective against other communicable diseases. The commission believes that the next great public health achievement can be the suppression of syphilis.

There is urged encouragement of epidemiological measures for the control of venereal diseases on a state-wide basis in coöperation with the medical profession.

Under public health nursing, it is recommended that as county health departments are developed throughout the state, each with an adequate staff of public health nurses, a qualified supervising nurse be placed in each unit under the direction of the county health commissioner, who shall: (a) be responsible for the work of staff nurses; (b) serve in an advisory capacity to and coördinate the work of all public health nurses in the county.

The commission report calls attention to the importance of public health education and recommends that the educational functions of the State Department of Health be reorganized for greater efficiency in interpreting the activities of the department and for greater service to the people; that necessary appropriations be secured for additional trained personnel and requisite facilities. It is suggested that the department assume responsibility for leadership in developing and establishing adequate courses in qualified schools and colleges of the state to familiarize students of medicine, dentistry, nursing, and teaching with the basic principles of public health. There is also recommended an inter-departmental committee to function in all matters having to do with health education in which more than one department of state government is concerned.—*Public Health in New York State*, Dept. of Health, Albany, 1932.

# LABORATORY

## DIPHTHERIA TOXOID PRECIPITATED WITH ALUM

### Its Preparation and Advantages

DEWEY M. WELLS, ARTHUR H. GRAHAM, M. D.,  
AND LEON C. HAVENS, M. D., F. A. P. H. A.

*Alabama State Board of Health, Montgomery, Ala.*

GLENNY and Barr<sup>1</sup> have recently described the complete precipitation of diphtheria toxoid with alum. This procedure differs from previous alum treatment<sup>2,3</sup> in that the toxoid is completely precipitated by the use of larger amounts of alum (2-10 per cent), the precipitate is separated from the supernatant by filtration and is then re-suspended in physiologic salt solution. They showed that the loss of specific antigen in the precipitate was less than 20 per cent while the decrease in non-specific nitrogen, as shown by tests of the supernatant broth, was as high as 70 per cent. Evidence has already accumulated that the antigenic value of toxoid is improved by the addition of alum. Glenny<sup>2</sup> has used it in the immunization of horses and Park and Schroder<sup>4</sup> have used a toxoid containing only 0.2 per cent alum and obtained results in guinea pigs and children which were superior to those with ordinary toxoid.

#### PREPARATION OF THE PRECIPITATED TOXOID

The toxoid precipitate used in the experimental work was prepared as follows: to 1 liter of lot 59, which contained 20 antigenic units per c.c., as determined by flocculation with antitoxin, was added 500 c.c. of a sterilized 4 per cent solution of aluminum-potassium sulphate. A coarse, flocculent precipitate formed at once which settled out in about 4 hours. The supernatant fluid

was siphoned off aseptically and the precipitate was made up to 1 liter with 0.85 per cent NaCl solution. After storage at 4° C. overnight the supernatant liquid was again siphoned off, and 0.85 per cent NaCl added to make the original volume of 1 liter. Biuret tests on the first supernatant indicated that about 70 per cent of the protein of the original toxoid remained unprecipitated.

Contrary to the observations of Glenny and Barr<sup>1</sup> we have encountered considerable difficulty in determining flocculation values with the alum precipitates dissolved in Rochelle salt (sodium potassium tartrate). Furthermore, as they have stated, different lots of broth require somewhat different treatment. We have, however, obtained results with 3 lots of toxoid which seem to be specific and which indicate that 75-80 per cent of the specific antigen is contained in the precipitate and that 50-70 per cent of the protein content of the whole toxoid is left in the filtrate.

In Table I are summarized the results of immunity tests in guinea pigs following a single injection of varying amounts of the alum toxoid. It is seen that not only did as small an amount as 0.1 c.c. cause the production in 4 weeks time of sufficient antitoxin to resist an injection of 5 m.l.d. of toxin, but that an injection of 0.5 c.c. uniformly protected pigs against large amounts of toxin, even as much as 100 m.l.d. In every instance the injections of toxin

were made 4 weeks after the injection of toxoid.

A single injection of the alum precipitate in guinea pigs produced such a high degree of immunity that our observations were extended to the effect of a single injection in children. If a considerable percentage of children could be made Schick-negative by a single injection, mass immunization could be greatly accelerated. A group of 98 children was selected on the basis of strongly positive Schick tests, and these were given a single subcutaneous injection of 1 c.c. of the washed precipitate. The Schick test, made 8 weeks after the injection, was negative in all but 6. There was a complete absence of severe reactions in this group, a further indication that the product was in a purer state.

There are several technical points in connection with the practical procedures still to be determined. As Glenny and Barr have shown, the optimum concentration of alum necessary to produce complete precipitation with a minimum amount of extraneous protein varies with different kinds of broth, and we have some evidence that it may vary with different lots of toxoid made with the same broth formula. We have thus far obtained fairly uniform results by preliminary titrations to determine the optimum amount of alum. The length of time required for precipitation to take place probably varies with different lots. Since the desired result is to obtain the maximum yield of specific antigen in the precipitate in as pure a state as is practically possible, the time should neither be too much shortened nor too greatly prolonged. We have confirmed Glenny's finding that the average time is about 2-4 hours; if the alum is permitted to act much longer than this the protein content of the precipitate increases without a corresponding increase in the yield of toxoid.

The advantages of the alum treated

TABLE I

IMMUNIZING ACTION OF ALUM TOXOID  
IN GUINEA PIGS

Toxoid Lot No.	Amount Toxoid Injected c.c.	M. L. D. Toxin	No. Pigs Tested	No. Pigs Surviving	No. Died Diphtheria Intoxication	Remarks
54	0.5	10	2	2	0	
54	0.1	5	2	2	0	
59	0.5	5	8	6	0	2 died of pneumonia
59	0.5	10	5	5	0	
59	0.5	20	5	4	0	1 died of pneumonia
59	0.5	50	5	5	0	
59	0.5	75	5	5	0	
59	0.5	100	10	10	0	

toxoid are obvious. The complete precipitation of the toxoid with re-suspension in salt solution results in a purified product, as evidenced by the amount of nonspecific protein discarded in the filtrate. The precipitation permits the use of low-grade toxin for the manufacture of toxoid, since the finished product can be concentrated to any desired extent by decreasing the volume of salt solution in which the precipitate is suspended. The chief advantage, however, is the production of immunity in over 90 per cent of children by a single injection. If further observations confirm these results, diphtheria immunization can be greatly accelerated.

#### SUMMARY

Complete precipitation of toxoid with aluminum-potassium sulphate results in a purified product. More than 50 per cent of the original protein remains in

the filtrate. A weak toxoid may by this procedure be concentrated to any desired degree.

The alum precipitate has a high antigenic value. A single injection of 0.5 c.c. in guinea pigs protects against 50–100 m.l.d. of toxin injected 4 weeks later.

A single injection of 1 c.c. in 98

Schick-positive children resulted in a negative test 8 weeks later in 92, 94 per cent.

## VITAL STATISTICS

### BIRTH AND DEATH CERTIFICATES AS PUBLIC RECORDS

J. V. DEPORTE, PH. D., F. A. P. H. A.

*Director, Division of Vital Statistics, New York State Department of Health, Albany, N. Y.*

AN inquiry addressed to the registration officials of all states (and to the District of Columbia) brought out a striking divergence in the practice of furnishing transcripts of birth and death certificates. A summary of the replies follows:

#### PROCEDURES GOVERNING THE ISSUANCE OF TRANSCRIPTS OF BIRTH AND DEATH CERTIFICATES IN CONTINENTAL UNITED STATES

(Information furnished by State Departments)

#### (1) *Records considered confidential under direct provisions in the law:*

##### (a) *All records*

Alabama—Applicant for certified copy must be "entitled to same."

Kentucky—According to law, "the confidential relation existing between a physician and his patients is extended to the birth certificates." (Quoted from letter.)

Maryland—Certified copies may be furnished any applicant "for proper purposes." The law of the State of Maryland also provides that "any county registrar, local registrar, deputy local registrar, or state registrar, who shall communicate to any person not

authorized to receive the same any of the personal or statistical facts recorded on his register, shall be deemed guilty of misdemeanor and on conviction thereof, shall be fined not exceeding \$300." Annotated Code, 1924, Section 28.

Nebraska—Certified copies may be furnished to any applicant "for any proper purpose."

New Mexico—The law gives power to State Board of Public Welfare to promulgate regulations to prevent "wrongful or improper use of the information contained" in certificates of births, deaths, and marriages.

New York—Certified copies must be supplied to any applicant unless the state commissioner of health "is satisfied that the same does not appear to be necessary or required for judicial or other proper purposes."

Texas—The law provides that certified copies shall be supplied upon request to "any properly qualified applicant." An amendment to the law forbids the issuance of "a certified copy of any birth or death certificate wherein a child or an adult is stated to be illegitimate unless such copy is ordered by a court of competent jurisdiction."

#### (b) *Only records of births or deaths of illegitimate children*

Minnesota  
Virginia  
West Virginia

(c) *Only original records that have been corrected*

Massachusetts—All records are open to public inspection "excepting in cases of original records that have been corrected; the corrected records are open to public inspection, but the original records that have been corrected are open only to inspection by the persons concerned or such officials whose duties would require that they may be inspected." (Quoted from letter.)

(2) *Records considered confidential under regulations of the Department of Health or an opinion of the State Attorney-General; no direct provision of the law:*

(a) *All records*

Florida	No. Carolina	Tennessee
Idaho	Ohio	Wisconsin
Iowa	Oregon	Wyoming
Louisiana	Pennsylvania	

(b) *Only records of illegitimate births*

Arkansas  
North Dakota  
Utah

(c) *Only birth certificates*

District of Columbia

(3) *No legal provision or state regulation. A number of replies stated that the requirement of a fee for a search or transcript acts as a deterrent in many instances where the motive of the applicant is mere curiosity:*

Arizona	Kansas	New Jersey
California *	Maine	Oklahoma
Colorado	Michigan	Rhode Island
Connecticut	Mississippi	So. Carolina
Delaware	Missouri	So. Dakota
Georgia	Montana	Vermont
Illinois	Nevada	Washington
Indiana	N. Hampshire	

\* The regulations of the department of health provide that a search must be "a proper one (in not being merely to gratify idle curiosity or for some scandalous object, or for a purpose in which the inquirer is not beneficially interested)." No reference is made to any restrictions upon the issuance of transcripts when the required fee is paid.

In only 7 states are the records of births and deaths shielded by law against indiscriminate inspection; it is interesting to add that in one of them, Maryland, the communication of any personal or statistical facts contained in the certificates "to any person not authorized to receive the same" is a mis-

demeanor and, on conviction, the registrar is subject to a fine not exceeding \$300. In 11 states the records are considered confidential on the basis of departmental regulations or opinions of attorneys general. In 7 states and the District of Columbia specified types of records, mainly those of illegitimate children, are protected either by law or regulation. In the remaining 23 states, no restrictions are imposed upon the issuance of transcripts other than the payment of legal fees and the convenience and dispatch of public business.

In an opinion, later upheld by the Court of Appeals, the Appellate Division of the New York Supreme Court stated that,

Publicity statutes . . . are common in this country, and they are usually couched in broad terms, but it is generally held that even under such statutes, the individual seeking an inspection must show that the information is sought for some legitimate and specific purpose, and that the gratification of mere curiosity or some speculative purpose will not suffice. What will be deemed a sufficient reason for the examination of any specified records must depend in each case upon its own peculiar circumstances. The department of health . . . differs in many respects from other municipal departments. In consequence of the nature of its duties it becomes the repository of the records concerning the most intimate affairs of the individuals resident within the limits of the municipality, and among these records are doubtless to be found many matters of no public interest, but which might, if disclosed to whomsoever sought to examine them, be used for sinister or unworthy motives. (Matter of Allen, 205 N. Y. 158.)

Certain items on birth and death certificates may be looked upon as being of legitimate public interest: the fact of a birth, the sex of the child, the name of the parents; similarly, the fact of a death, the name, age, and sex of the deceased. Other items, however, do not belong in the same category. The public good, clearly, does not require that an inquisitive person be told the age of her neighbor, or given information re-

garding a birth to an unmarried woman, or furnished with any of the facts contained in the medical part of a death certificate in violation of the accepted practice of all civilized countries which protects the knowledge gained by a physician in the course of his professional duties. In the words of the Court of Appeals of the State of New York:

The disclosure by a physician, whether voluntary or involuntary, of the secrets acquired by him while attending upon a patient in his professional capacity *naturally shocks our sense of decency and propriety* and this is one reason why the law forbids it. The form in which the statements are sought to be introduced is of no consequence, whether as a witness on the stand or through the medium of an affidavit or certificate. *Davis vs. Supreme Lodge, Knights of Honor* (165 N. Y. 159).

For many years, committees of the American Public Health Association, in coöperation with other organizations, have labored over the essential problem of improving the accuracy of certified causes of death. Finally in January, 1932, in another important decision, the same view was emphatically reiterated by the Appellate Division of the New York Supreme Court: \*

The reason assigned for the necessity of such disclosure of official documents of the department of health does not outweigh the importance of keeping the contents of such papers secret.

To divulge to the world the secrets of a patient would not only be shocking, but against public policy.

A uniform classification of causes of death and treatment of joint causes is, of course, essential, but it must be based on the premise that the statement on a death certificate represents the true judgment of the certifying physician. When this judgment is confided to the care of a registration office, is there not

an implied pledge that the physician's statement will be safeguarded and the information used only for statistical record and scientific research?

The accuracy of our natality and mortality statistics is directly related to the accuracy of the information contained in the birth and death certificates and this can be achieved in full measure only through the general acceptance of the principle that facts which relate to "the most intimate affairs of individuals" must be treated confidentially.

**Twenty-Five Years of Public Health in Pennsylvania, 1906-1930**—Vital statistics records for the Commonwealth of Pennsylvania cover the years since 1906 when state-wide registration was begun. These reports indicate that considerable progress has been made in many endeavors of public health workers. Just what has been accomplished can be illustrated best by the birth and death figures for this period.

In 1906, there were 167,265 children born in the state. In 1930, the number was 189,573. Although this indicates an actual gain, the rates show a constant decline. The 1906 birth rate per 1,000 population was 23.4. The peak was reached in 1914 (27.0) and a gradual decrease since that time has brought the rate for 1930 down to 19.6. This diminution is not confined alone to Pennsylvania, for the entire United States Registration Area is experiencing a similar loss. Stillbirths, which are considered separately from both natality and mortality statistics, have diminished correspondingly. Twenty-five years ago there were 8,679 stillbirths with a rate of 51.8 per 1,000 live births, and in 1930 the total was 7,957, giving a rate of 42.0.

It is interesting to note the change in the ranking of the leading causes of death during this interval. Tuberculosis (all forms) held first place in 1906.

\* Health Department's Records Confidential, *Week. Bull. New York City Dept. of Health*, Feb. 6, 1932.

By 1910, it had dropped to 3d and 1925 found it in 6th place, the position it maintained in 1930. Heart disease gained the lead in 1915 where it has remained with a few exceptions. Nephritis, cerebral hemorrhage, pneumonia, diseases of early infancy and cancer, although varying in order, have been among the 7 most important causes of death during the entire 25-year period.

With the exception of 1918 when the severe influenza epidemic resulted in an unusually high toll, the general death rate has declined steadily from 16.0 per 1,000 population in 1906 to a preliminary rate of 11.6 for 1930. By the use of antitoxin, toxin-antitoxin and the more recently developed toxoid, the diphtheria mortality has been lowered from 34.1 per 100,000 population (1906) to 5.2 (1930). Due to the frequency of smallpox vaccination, deaths from smallpox are rare—only 1 since 1925. Because of strict vigilance over quarantine and the widespread education of the people concerning communicable diseases, the losses from measles, scarlet fever, and whooping cough have decreased. Since the sources of milk and water supplies have been carefully supervised and inspected, the disorders which are spread by such carriers have been restricted. Typhoid fever has been reduced from 54.8 per 100,000 population in 1906 to 2.6 in 1930. Diarrhea and enteritis under age 2 has also fallen from 137.2 to 23.3 per 100,000 population.

Infant mortality rates show a great reduction. In the first year of statewide registration, 27,908 children under 1 year of age died, as compared with 12,887 in 1930. The contrast between the rate of 167 per 1,000 live births for the former year and 68 for the latter shows more clearly the true gain.

Great progress has been made in the control of the respiratory diseases, most important of which is pulmonary tuberculosis. From this cause, there were

9,258 deaths with a rate of 129.6 per 100,000 population in 1906, which by 1930 had been reduced to 5,295 with a rate of 54.0. Pneumonia (all forms) and bronchitis have responded also to the attacks made against them. On the other hand, the trend of influenza has been slightly upward. Safety propaganda, together with the development and use of safety devices, has been responsible for the decreasing rate for accidental deaths. This is due in large part to the reduction in mine and quarry disasters. The highest rate recorded for deaths from accidents in this class was 21.2 per 100,000 population in 1907; the lowest, 8.2 in 1930. The rate for fatal railroad injuries has dropped from 30.2 in 1906 to 5.4 in 1930. The death rate from automobile accidents, however, is an increasingly important factor in the general mortality. In 1906, there were 19 persons killed in automobile accidents, with a rate of 0.3 per 100,000 population. Since that time, because of better roads and cheapness in production, motor vehicles have become more numerous and incidentally more dangerous, so much so that in 1930, 2,424 persons in Pennsylvania lost their lives as a result of automobile accidents, bringing the death rate from this cause up to 25.1.

The degenerative diseases have been climbing upward steadily. Heart disease, the leading cause of death, has increased from 133.5 per 100,000 population in 1906 to 239.1 in 1930. During the same period, cerebral hemorrhage has risen from 73.1 to 85.5; cancer from 58.9 to 100.0; nephritis from 84.3 to 104.3; diseases of the circulatory system (exclusive of heart disease) from 16.2 to 30.3; and diabetes from 10.5 to 22.4. Maternal mortality has maintained an even trend over the 25 years under consideration. In 1906, 1,213 women died from causes associated with childbirth. In 1930, there were 1,127. The rates were 6.9 and 5.7 per 1,000

total births, respectively. A large proportion of these deaths were due to puerperal septicemia—39.2 per cent the first year and 37.4 per cent the last.—*Vital Statistics*, Emlyn Jones, M.D., Chief, Bureau of Vital Statistics; *Pennsylvania's Health*, 10: 77-78 (Jan.-Feb.), 1932.

**Post-Vaccinal Encephalitis in Holland**—According to a report by the Inspector-General on Vaccination in Holland, there were 866,100 vaccinations performed in that country from 1924 to May, 1931, and of these, 186 cases were followed by encephalitis, which is equivalent to 1 case of encephalitis to every 4,656 vaccinations.

A special commission appointed to examine each case classified them in 4 groups—namely, (1) undoubted cases; (2) almost undoubted cases; (3) doubtful cases; and (4) very doubtful cases. In the statistics drawn up by the Inspector-General only the first 2 groups were considered. Among about 62,000

children vaccinated in the 1st year of life, there were only 3 cases of encephalitis, and among 137,000 children between the ages of 1 and 2 years only 5 cases, or 1 case among 25,000 vaccinations in children under 2 years of age. All these patients recovered without sequels. Among 660,000 children between 2 and 11 years there were 159 cases, or 1 in 3,570; 55 of these died, a proportion of one death to 15,749 vaccinations. In 1930, 5 cases occurred among 27,131 vaccinations, or one case among 5,426 vaccinations. There has been a great decline in the number of vaccinations after the small outbreak of smallpox in the second half of 1929, and as compulsory vaccination at school age has been temporarily suspended, no case has occurred between May, 1930, and May, 1931, although between 24,800 and 25,000 vaccinations were performed during that period.—*Bull. Office Internat. d'Hyg. Publ.*, Oct., 1931, p. 1804; *Canad. M. A. J.*, 26: 301 (Mar.), 1932.

## PUBLIC HEALTH ENGINEERING

### AN INVESTIGATION OF THE MONTREAL TYPHOID EPIDEMIC OF 1927\*

H. D. PEASE, M. D., F. A. P. H. A.

*New York, N. Y.*

A PRIMARY outbreak of approximately 2,600 cases of typhoid fever reported during March and April was followed by a remission of 3 weeks and a sharp recrudescence of nearly as many cases in the following month of May. A total of 5,353 cases developed

with a mortality of approximately 10 per cent.

Clear indications showed within the first week of reports that the disease was milk-borne and probably attributable to the distributions of the products of two associated milk companies (M and N). Notice was given by the Health Department Director about March 12 to increase the temperature of pasteurization of all milk in Montreal above that re-

\* Abstract of paper read at a Joint Session of the Laboratory and the Food, Drugs and Nutrition Section of the American Public Health Association at the Sixtieth Annual Meeting at Montreal, Canada, September 16, 1931.

quired, 142° F. for 30 minutes, to 146° or over. A start in the decline of cases occurred about 2 weeks later. Approximately 75 per cent of the reported cases were among consumers of M and N milk. These companies supplied but one-eighth of the total milk supply of the city.

The geographic distribution of cases (pin map) and that of the milk supplies of M and N companies were in close harmony, and the earliest cases with the preponderance of incidence were in children and youths.

There was an entire absence of any such geographic relation between the varied distribution of the three public water supplies and the intensities of incidence of the infection. There was also an absence of bacteriological evidences of water supply pollutions.

A discovery was made in April that a man "C"—the supervisor of the pasteurization equipment in the M and N plants—from January 30, 1927, was a typhoid carrier, and he was discharged April 15. A man "B" who succeeded "C" as operator of the same equipment retired from the M and N plants on April 25 by reason of illness. On May 20 there was obtained a positive Widal test with his blood.

The carrier "C" and this incipient case successor, "B," were in direct charge and operation of the holding tanks, regenerator, cooler and filling mechanisms, each of which possessed certain defects of structure. Also, the records and the evidence as to the methods of cleansing and operation of them by these infected workers indicated the existence of several well defined opportunities for those degrees and times of typhoid infections of the pasteurized milk as might readily account for the peculiarly spaced incidences of the outbreak and its recrudescence.

Reports of procedures followed by employees in the pasteurizing room showed deficiencies in operating meth-

ods of a serious nature, such as standing on the edge of the cooler trough with dripping boots, stirring the pasteurized milk with a dipper picked up from the floor, immersing the hands in the cooled milk to adjust the bulb of a thermometer.

Temperature records were available and led to interpretations of operating conditions as they pertained to the holding tanks, and indirectly to some of the other apparatus. These, together with accurate temperature studies made under ideal operating conditions, presented a picture in which the typhoid carrier and his successor had rôles of major importance.

No attempt was made to assume any specific course of events which led to the infection of pasteurized milk in the M and N plants. Several hypothetical channels of readily recognizable causative potentialities may be listed as follows:

Infection of the milk holding tank by plant employees operating in the pasteurizing room, followed by incubation in the tanks. Lapses in heat treatment of the tanks resulting in failure to sterilize them. Infection of the pasteurized milk and lack of destruction of typhoid organisms because of low temperatures in the first milk and resulting in the infection of the foam. In addition, leakage of this first underheated and possibly infected milk through outlet valves and possible incubation in the pipe lines. The relation between lapses in hot cleaning and pasteurizing temperatures shows most striking correlations with the rises and declines in the outbreak and its recrudescence.

The regenerator also played a potential rôle in both infection and the incubation of any already infected pasteurized milk under certain conditions of operation. It, in itself, could have been directly infected, as typhoid carrier "C" was immediately responsible for its preparation for the day's run every morning he was on duty. The infection could also have readily incubated in it during the run or by reason of lapses in hot cleaning during the night.

The cooler, handled and especially as subjected to gross treatment during use by the typhoid carrier, could have been infected with resulting incubation and heavy inoculation of

the milk. Incubation of colon bacilli was proved in the cooler on surfaces, the drippings from which went into the pasteurized milk.

Cream might have contributed to the second outbreak by becoming infected in a milk storage tank, and by subsequently infecting the milk through a leaking valve in a connecting line, or by the passage of milk through a pipe previously used for cream. The infected cream itself may have been responsible for a certain number of cases.

While these possibilities are specifically listed, the epidemic may have been caused by a combination of them or by other unrecognizable factors operating within the plants.

In consideration of the possible rôle of country infected raw milk in the causation of the outbreak it may be said that while there were shown to exist potentially dangerous pollutions of utensil wash water supplies employed at some of the country receiving stations of the M and N Companies, diligent search for centers or individual typhoid cases in the country milk sheds of the M and N Companies failed to re-

veal any origins earlier than the time of the fully established outbreak in the city or having any direct causal relation thereto. The few cases suspected of such a relation were given special consideration and nothing was found to warrant attributing the causation of the outbreak to them. Also the records of the M Company indicated satisfactorily that no diversion of raw milk from the process of pasteurization occurred during the period of the epidemic. Even if raw milk in substantial amounts had been so diverted and distributed without pasteurization, it would have been subjected of necessity to some of the conditions found to afford ample opportunities for the typhoid infection of the pasteurized milk in the plants.

The evidence found has been wholly on the side of the infection and probable incubation of pasteurized milk and/or other dairy products distributed by the M and N Companies as the causative factors of the primary outbreak and its recrudescence.

NOTE: Full report published in pamphlet form by the Provincial Bureau of Health of the Province of Quebec, Quebec, Canada.

## THE STATE BOARD OF HEALTH OF MISSOURI

### DIVISION OF PUBLIC HEALTH ENGINEERING AND SANITATION

### RECOMMENDED SPECIFICATIONS COVERING SANITARY CONSTRUCTION FEATURES OF DRILLED WELLS

(Revised 1932)

1. *Samples of Cuttings*—At least 1 week before starting to drill the well, the driller shall send a written request to the State Geologist, Rolla, Mo., who will furnish a set of small sacks, a drill record book, and a letter of instructions regarding the collection and handling of drill cuttings. The well driller shall save a sample of cuttings from every 5 ft. and place them in the sacks, properly labeling same. These cuttings shall be taken from the *driller* and not from the slush pit. The sacks containing the cuttings shall be sent to the State Geologist at Rolla each day until the casing is set, after which they shall be sub-

mitted weekly. These cuttings shall be examined by the State Geologist or his assistants.

2. *Casing*—Upon the basis of available records, the State Geologist will recommend the depth of casing advisable to shut out effectively surface water and shallow ground water that may be contaminated. The casing shall be extended to at least this depth, and deeper if necessary, so as to case off all openings or soft or broken ground. When the drill hole reaches the depth at which the casing shall be set as recommended, drilling shall cease until the casing is set and the seal has been tested to demonstrate that it is water-tight.

The well shall be cased with a screw joint steel or wrought iron pipe of corresponding size and weight of casing, installed in a water-tight manner. The pipe or casing shall conform to the following minimum specifications for weight and thickness:

Size Inches	Thick- ness Inches	Wt. (lbs.) per ft. with Threads and Couplings *	Threads per inch
4	0.23	10.8	8
5	0.25	14.8	8
6	0.28	19.1	8
7	0.30	23.7	8
8	0.32	28.8	8
9	0.34	34.1	8
10	0.36	41.1	8
11	0.37	46.2	8
12	0.37	50.7	8

\* This weight is based on 20-ft. lengths. A 5 per cent variation is permissible.

When the water is known or suspected to be corrosive, the casing shall be of corrosion-resistant material and shall be protected from the action of corrosive waters. In order to protect the casing, the hole shall be thoroughly mudded with clean mud-laden fluid or preferably the casing shall be sealed by the use of cement applied in an approved manner. The cement shall be placed between the outside of the casing and the wall of the hole throughout the entire length of the casing or at least through those horizons which yield highly mineralized water.

The well casing shall be extended to a point not less than 6 in. above the elevation of the finished pump room or pump pit floor, and shall be provided with a thread at the top.

3. *Seal*—A satisfactory seal shall be made or installed at the bottom of the casing by one of the following methods:

(a) Setting the bottom of the casing on a shoulder in the well made by reducing the size of the drill hole, and sealing with a lead packer or cement grout applied by an approved method. An approved method of sealing the casing with cement requires that the cement be forced up behind the shoe several feet.

(b) Driving or rotating the casing into clay, shale or similar sealing formation.

(c) Installing an expanding rubber packer.

The seal shall be tested by bailing out the well and making sure that there is no leakage into same over a period of not less than 12 hours. When cement grout is used for sealing

the casing, the test for leakage shall not be made until the cement grout has set up. When no appreciable amount of water has been encountered up to time of sealing, a sufficient quantity of water to fill the space between the casing and drill hole shall be run into the annular space on the outside of the casing to test the seal.

The well casing shall be tightly sealed to prevent the downward percolation of surface water or other undesirable waste around the outside of the casing. This can be accomplished by thoroughly puddling the space between the outside of the casing and the wall of the hole with clay and sealing the upper 5 ft. with concrete. Whenever a gravel wall well or gravel packed well is constructed the outer casing shall not be removed from the hole but upon the completion of the well it shall be sealed in place in the usual manner.

4. *Water Analysis*—When a waterbearing stratum, furnishing the required volume of water, is encountered at a satisfactory depth, samples of water shall be collected at the end of the test pumping run and submitted to the State Board of Health, in containers provided, for complete chemical and bacteriological analyses to determine the suitability of the water for a general city supply.

Before setting the pump for the test run, the well shall be thoroughly disinfected with calcium or sodium hypochlorite. In case the permanent pump is not used for the test run, the disinfection shall be repeated just previous to the installation of this pump. Disinfect the well with fresh dry chlorinated lime (also called calcium hypochlorite or bleach powder) made into a solution as follows:

(1) Two pounds of the disinfectant shall be used in order to assure satisfactory results.

(2) Make the powder into a smooth paste with a small amount of water, crushing out all lumps.

(3) Dissolve the paste in about 2 gal. of water.

(4) Allow solution to settle; pour the clear solution into the well; and if possible mix with the water in the well.

(5) Allow the solution about 2 hours' reaction time before pumping the well.

Other prepared chlorine compounds may be used as a substitute for chlorinated lime provided sufficient quantity is used to make available 0.5 lb. of free chlorine.

5. *Records*—The driller shall note in the drill record book the location and depth of any openings or soft or broken ground encountered, together with complete information on the depth of casing, method of sealing same, and result of seal test. Also, the driller shall note in the drill record book the depth at

which water is encountered, the static water level as the drilling progresses and at the completion of the well.

Immediately on completion of the well, and prior to completion if requested, the driller shall forward all samples of cuttings not previously submitted and the drill record book to

the State Geologist, who will correlate same and furnish the owner with a copy of the completed log of the well.

6. *Approval*—These specifications shall be carried out in a manner satisfactory to the State Board of Health of Missouri, before this portion of the work is accepted.

## RECOMMENDED SPECIFICATIONS COVERING SANITARY FEATURES IN THE INSTALLATION OF WELL PUMPING MACHINERY (Revised 1932)

A. The use of a well pit or subground-level pump room shall be avoided wherever practical on account of the possibility of stoppage of the drain or ejector and neglect to replace the well top seal after making repairs.

B. Where the pump is installed without a pit—

1. The pump shall be installed on a concrete base of sufficient height to permit the outside casing to extend not less than 6 in. above the pump room floor, and to enable the installation of a suitable connection as noted under B-2.

2. The annular opening between the outside casing and pump column shall be closed by means of a suitable water-tight connection which will effectually prevent waste water, oil, insects or other contaminating material from entering the well.

C. Where the pump is installed with a pit or in a pump room below the ground level—

1. The sides and bottom of the pit or pump room, below the ground level, shall be constructed of water-tight concrete. The pit shall be left uncovered to permit easy inspection by the pump operator, and shall be surrounded by concrete curb at least 6 in. high and a pipe railing.

2. The annular opening between the outside casing and pump column shall be closed by means of a water-tight connection capable of withstanding for 24 hours, without leakage, the water pressure resulting from complete filling of the pit with water. The types of connections approved are given below in order of preference.

a. An all flanged or threaded connection.

b. A stuffing box connection.

c. Metal to grouted cement connection with suitable gasket (not rubber); to be used only when joint carries weight of pump column and the pump is rigidly supported to prevent vibration.

Any vents provided for the well shall be

extended by a pipe with screw or flange connections to a point above the floor level. A return ell shall be screwed on the upper end of this pipe, and screened.

3. Drainage shall be provided for the pump pit or pump room by one of the following methods:

a. By means of a drain consisting of a sewer pipe, not less than 6 in. in diameter, with cemented joints, installed in a straight line and on an even grade of not less than 0.6 ft. per 100 ft., with a concrete bulkhead at the outlet to insure an open discharge at all times; provided that under no conditions shall this drain receive sewage, or be connected to a sewer, and that the bottom of the pit so drained shall be above the high water level in any adjacent watercourse.

b. By means of a pump or ejector drawing from a sump of not less than 12 cu. ft. capacity situated so as to collect all waste water. This pump or ejector shall operate automatically or be connected to some moving part of the pump head, so as to operate continuously with this pump, and shall discharge above the pump room floor level into a suitable drain at a point safely removed from the pump pit or pump room.

4. The bottom of the pit or pump room shall be sloped away from the top of the well casing toward the drain or sump with sufficient grade to insure ready flow. At least 12 in. difference in elevation shall be provided between the top of the well casing and high water level in the sump.

D. A separate pump column, suction or discharge pipe shall be installed inside the well casing in all instances, whether the well is to be pumped by suction, air lift or deep well pump.

E. These specifications shall be carried out in a manner satisfactory to the State Board of Health of Missouri, before this portion of the work is accepted.

# INDUSTRIAL HYGIENE

**The Ventilation of Factories and Workshops**—Section 7 of the Factory and Workshop Act, 1901, requires that in every workroom in a factory or workshop sufficient means of ventilation must be provided and maintained, with certain further special conditions to meet certain special hazards. There is, however, a more important provision, under Section 79 of the Act, which enables the Secretary of State to make such regulations as appear to him to be reasonably practicable and to meet the necessity of the case. Injury to health must be shown to exist in a particular manufacture or process, as in a report from one of the medical inspectors. In the case of dispute and where the matter cannot be settled by conference with all parties concerned, the draft code must be referred to an arbitrator appointed by the Secretary of State. Many codes of regulations relating to different industries and processes have been established in this way.

Various codes provide for at least 6 changes of air per hour in an ordinary workroom, but cannot of course be applied to workrooms ventilated only by natural means. Yet, in warm weather in small and moderate sized rooms, provided the windows or other ventilators are of sufficient size, properly distributed and freely used, the air will normally be changed more than 6 times per hour. Often the area of window opening is too small; at least 5 sq. ft. of opening per 100 sq. ft. of floor area should, if possible, be provided.

In dealing with injurious dust, gas or vapor rising from manufacturing processes, 3 methods of prevention obtain: (a) fully enclosed machines, (b) damp processes, and (c) mechanical extrac-

tion.—Leonard Ward, *J. Roy. San. Inst.*, 52, 5: 196–200 (discussion 214–216) (Nov.), 1931.

E. R. H.

**Air Conditioning Hut**—Starting with the air in the hut cool and still, it is made to circulate among the visitors present by starting the fan, which increases the sensation of coolness although the actual temperature of the air remains the same. By standing between the electrically heated panels, however, the body receives radiant heat, which compensates for the heat delivered up to the moving air, and this combination of radiant heat with air at a comparatively low temperature moving at a reasonable velocity produces a very favorable sensation.

As soon as humidity is produced by means of steam jets, the temperature of the air is also slightly raised owing to the introduction of steam and there is at once a feeling of lassitude as the cooling power of the air is reduced (sufficient heat is not removed from the body). Starting the fan under this condition immediately gives a sensation of comfort although the temperature and humidity remain the same as before. If the fan is stopped and humidification continues to a point at which fog is produced, the atmosphere becomes oppressive but there is immediate relief in again starting the fan.

By keeping the air in circulation through the convection heaters, its temperature gradually increases, which causes a fall in the relative humidity, but so long as the air is moving the conditions are pleasant. In contrast, under the same conditions of humidity and temperature but with still air, discomfort is felt. If at this point the hu-

midity is increased, the discomfort is increased, as there is produced an atmosphere which is both very warm and very humid, and without air movement. The pulse rate and the breathing rate are found to increase, but if now the fan is started there is a general feeling of relief, the breathing becomes more free and yet the temperature and humidity have remained the same.

When the warmed and humidified air is allowed to remain stagnant for a few minutes, there is a considerable difference in temperature at different levels. The upper air is much warmer than the air near the floor. This condition produces an uncomfortable feeling of oppressive warmth round the head and coldness of the feet.

The principles emphasized in the hut demonstration are capable of wide application in industry. It is shown that for both comfort and efficiency the heat removed from the body must balance the heat produced when working. An atmosphere incapable of removing sufficient heat can be improved if the air is kept in motion. Where the heat loss from the body is excessive the remedy is a supply of radiant heat.

The air conditioning hut has served the useful purpose of bringing these facts to the notice of employers and others who had been unable to produce satisfactory conditions, consistent with the carrying on of manufacturing processes by the application of older ideas of ventilation.—Hilda Martindale, Home Office Industrial Museum, *Annual Report of the Chief Inspector of Factories and Workshops* (Great Britain), 1930, pp. 78-81.

E. R. H.

**Ventilation as a Physiological Problem**—Ventilation, derived from the Latin *ventilare*—"to fan"—means no more than the maintenance of air movement. Nevertheless, the common conception of effective ventilation is that of an adequate supply of fresh and

of pure air. The widespread belief in the necessity for freshness and purity of the ventilating air has held until recent times. It is now realized that the chief function of ventilation is the provision of such an external environment that the body may, in its turn, maintain the physiological integrity of its internal environment—and that with the minimum of strain.

In a series of experiments, Leonard Hill in 1913 finally disposed of the claim advanced that expired air contains injurious organic matter other than bacteria.

Even when at rest, the human body produces no inconsiderable quantity of heat, and all excess must be got rid of; otherwise ultimate destruction of the body occurs more surely and more rapidly than with the retention of any other waste product. At least three-fourths of the heat produced in muscular effort is a waste product to be removed; otherwise heat stroke may ensue. The more subtle or premonitory stage of heat-stagnation is less obvious and is also more frequent. The strain is thrown on the cardiovascular system, while warm moist atmospheres also affect the mucous membranes of the respiratory tract.

Clothing aggravates the stagnation of heat. The part which clothing may play in the heat loss of the body is of paramount importance. It is the beneficial effects of air movement which are largely negated by unsuitable clothing. A human being is able to adjust himself to his surrounding within fairly wide limits and also has power of acclimatizing himself. In still air the sensory nerves of the skin are not stimulated, by which an increased rate of sweat production is brought about in acclimatization.

Orenstein and Ireland showed that the efficiency of natives in the Rand mines was greatly improved by increase in the cooling power of the environment. For

sedentary work, the dry kata-thermometer should be 6, for light muscular work 8, for heavy muscular work 10, while corresponding figures for the wet kata are 18, 25 and 30, respectively. Many other investigators have found similar kata conditions necessary.

The new orientation in the scientific attitude to ventilation seems to be thoroughly justified both by physiological experimentation and by practical experience in industry.—R. C. Garry, University of Glasgow, *J. Roy. San. Inst.*, 52, 5: 208–213 (discussion 214–216) (Nov.), 1931. E. R. H.

**Vaccine in the Prevention of the Common Cold. An Experiment—**An experimental study was made to determine the effects of vaccination on the incidence and duration of common colds. Eighty medical students were vaccinated with a prepared, partially detoxicated vaccine, and 82 medical students acted as controls.

The statistical results of the experiment show little, if any, improvement as regards common colds in the experimental group as a whole compared with the control group. Individuals in the experimental group appear to have received some benefit. This is in accord with the findings that the group as a whole was not completely desensitized to the particular antigens used. Better results may be possible with an increased dosage of the vaccine or by employing with each individual the particular antigens to which he may be shown sensitive.—W. E. Brown, *Am. J. Hyg.*, 15, 1: 36–63 (Jan.), 1932.

E. R. H.

**Vasomotor Reactions to Localized Drafts—**When the unclothed body was exposed to uniform atmospheric conditions the average temperature of the skin varied directly with the effective temperature of the atmosphere. The skin temperature dropped about 1° C.

for every 2° F. drop in effective temperature.

Under uniform atmospheric conditions, the average skin temperature was 25.8° C. for *cold*, 29.5 for *cool*, 32.1 for *warm* and 33.5 for *hot*, while variations amounted to as much as plus 4 to minus 8.3 for *cold* to plus 1.9 to minus 1.6 for *hot*, depending upon the part of the body whose skin temperature was taken.

Under varying atmospheric conditions affecting the whole body uniformly, the temperature of the nasal mucosa followed that of the skin of the face, ranging about 3° below it. A localized draft on the head caused a fall in the skin temperature of the face and in the temperature of the nasal mucosa with less marked fall in the temperature of the mouth.

Chilling of the feet by local drafts did not materially affect the skin temperature of the rest of the body, but it caused a distinct rise in the temperature of the nasal mucosa. One subject showed entirely abnormal responses differing sharply from those found for the other six subjects.

The results correspond with those of Hill and Muecke, of Grant and his associates, of Azzi, and of the New York State Commission on Ventilation, in showing that chilling of the body surface results in contraction, and ischemia and dryness of the mucous membranes of the nose.

Nothing was found to indicate that localized drafts differ in respect to vasomotor reactions from uniform chilling of the body surfaces as a whole, or to suggest a special influence on respiratory infection. Chilling of the head caused less disturbance in the nose than exposure of the entire body to a corresponding effective temperature, while chilling of the feet actually caused dilation of the blood vessels of the nose and throat.

The experiments were carried out on a small group of normal young men

without clothing. While the effects of drafts at higher room temperatures might yield quite different results. The significant thing is that the investigation does not confirm the general belief that chilling of the feet is especially harmful.—C.-E. A. Winslow and Leonard Greenburg, *Am. J. Hyg.*, 15, 1: 1-35 (Jan.), 1932. E. R. H.

**Influence of Infra-Red Radiation in Relation to Ventilation and Heating**—Many people feel stuffy and uncomfortable in a closed room warmed by a plenum system, or by dark and dull red sources of heat. The feeling of stuffiness has been attributed to some unknown X quality of the air, to its ionization, or to addition of vapor arising from the roasting of dust particles on heating surfaces.

Some have thought that the air is made over dry, and have placed bowls of water on stoves or in front of the old-fashioned gas fire. No evidence of any significant alteration in the humidity of the air has, however, been forthcoming, and proof of significant change in ionization has failed to appear.

The conclusion to be drawn from personal experiments is that stuffy feelings are produced by dark or dull heat rays acting on the skin, and reflexly through the nerves of the mucous membrane of the nose. It is the longer infra-red rays which produce this effect, rays which are absorbed by a thin film of water, and which have almost no power of penetrating the outer surface of the skin. These rays are largely screened off from sunlight by the water vapor in the atmosphere, but are abundant in a green-house heated by sunlight since they are given off therein by the heated surfaces, hence the stuffy effect noted.

The close relation between the state of the skin and asthma is generally recognized. Some 60 per cent of asthmatics are said to suffer from some form of dermatitis, and many asthmatics are benefited by light baths. Storm Van Leeuwen has found that fan impulsion of pure dust-free air through their sleeping compartments relieves many asthmatics and chronic bronchitics. It may well be that the effect is not wholly due to dust removal, but partly to a cooling of the face, which antagonizes the dark heat rays in a closed room. By a ventilation of rooms, adequate to remove infecting microbes and prevent the congestion effect of long dark heat rays on the nose, I believe, the number of colds may be reduced. It is known that open air workers suffer very little from colds, and have a low death rate. Proper feeding with plenty of milk, butter, fruit and vegetables is, of course, also required to keep down infection. If the congestion and closing of the nasal passage is, as I think it is, a sign of ill ventilation, then it follows that enough cool air should be sent through every room to cool the face and counteract the effects of the long infra-red rays.

—Sir Leonard Hill, *J. State Med.*, 39, 12: 683-687 (Dec.), 1931. E. R. H.

**Factors in the Production of Nervous Lesions Following Electric Shocks**—In the present study rats were used as the experimental test animal. The author's summary follows:

When the current from a 1,000-volt alternating or continuous circuit was allowed to flow through the preparation for one second, abnormalities in the nerve cells of the brain or the spinal cord were demonstrated only in areas traversed directly by the current pathway. The electric current produced damage to nerve cells in experiments where heat production was negligible. If a large current flows through the body for a considerable time, there is marked heat production which causes changes in nerve cells indistinguishable from those produced by the electric current alone.

—Orthello R. Langworthy, *J. Indust. Hyg.*, 14, 3: 87 (Mar.), 1932. L. G.

# FOOD AND NUTRITION

**A Bacteriological Study of Decomposing Crabs and Crabmeat—**Bacteriological studies of Chesapeake Bay crabmeat were made on samples of crabmeat from Maryland and Virginia purchased on the open market, as well as on some whole live crabs. Spoilage experiments were conducted at room temperature and at refrigerator temperature. The author states that the decomposition is due to progressive proteolysis associated with a rapid increase in ammonia content. The predominating bacterial types encountered were the Gram-negative non-spore-forming bacilli, and the Gram-positive streptococci. Decomposition experiments in which sterile crabmeat was inoculated with pure cultures of *Proteus vulgaris* resulted in a proteolytic decomposition of the meat, with the pH changing from 7.0 to 6.8. In the spontaneous decomposition of crabmeat, the pH changed from slightly alkaline to pH 8.2–8.6.

The writer concludes that the decomposition was due primarily to the action of the *Proteus* group, possibly supplemented by some of the *Pseudomonas* and *Flavobacterium* groups. There apparently is no relation between the "age" of decomposition and total aerobic counts. There is no close relation between the "age" of decomposition and the pH value. Spore-forming anaerobes are not concerned in the decomposition. Spoilage at refrigerator temperature fails to show an increase in the *B. coli* score. Bacteria belonging to the following genera have been isolated: *Escherichia*, *Proteus*, *Zopfius*, *Alcaligenes*, *Flavobacterium*, *Achromobacter*, *Pseudomonas*, *Micrococcus*, *Sarcina*, and *Streptococcus*.

The delicate Nessler ammonia test is tentatively proposed as a means of detecting ammoniacal spoilage in crabmeat during the incipient stages before macroscopic signs of proteolytic decomposition are apparent. No correlation is made between the type of spoilage studied and the production of toxic substances.—Marvin M. Harris, *Am. J. Hyg.*, 15: 260 (Jan.), 1932.

**The Poisonous Principle of Lathyrus and Some Other Leguminous Seeds—**The seeds under consideration in this article are *Lathyrus sativus* and *cicera*; *Ervum lens* (lentils); *Pisum sativum* (the common cultivated pea); *Soya hispida* (the soya bean); *Vicia sativa* (tares); *Cajanus indicus* (the pigeon pea); and *Ervum ervilia* (the bitter vetch). In all these seeds the poisonous body is an acid and apparently the same acid in all. In large doses its action on frogs is always qualitatively the same, namely, depression of the brain and spinal cord, succeeded, if the dose be not lethal, by more or less increase of spinal reflexes, and the motor nerves are not paralyzed. The muscles are also poisoned, more especially in the area of the injection but also more widely through the blood. With very small doses the depression stage may be hardly noticeable and there is an equally slight increase of spinal reflexes.

Rabbits (herbivora) are very insusceptible, but with large doses show a certain amount of weakness of the legs.

In monkeys after a large or frequently repeated smaller dose, the symptoms broadly are those of depression and irritation of the brain and cord, but in detail they vary somewhat. Sometimes drowsiness and lethargy are very promi-

nent; sometimes weak tremors or coarse jerking of muscles, or clonic or tonic convulsions of groups of muscles in rapid succession and involving the whole body; sometimes a shaking palsy like paralysis agitans. But always there is marked paresis of the motor tracts and muscular weakness. The more powerful flexors and adductors overcome the extensors and abductors, giving rise to flexion of the joints and adduction of the limbs. One limb is often earlier and much more affected than the others. The chief effect, therefore, is on the cerebrum (fore-brain, motor areas and basal ganglia) and the spinal cord, but it is not always the same part which is chiefly affected and hence the considerable variation in symptoms.

In using 15 different lots of lathyrus it was found that they vary very greatly in toxicity, and this is probably true also of other peas and accounts no doubt for the cases of poisonings which have occurred occasionally among farm stock with soya meal, and with the bitter vetch and lathyrus itself. A lentil feeding experiment on a monkey shows that an individual sample may be very poisonous.

Like opium, coca, tobacco and many other drugs of the same kind, these leguminous seeds may be classed as stimulant-narcotics, that is, stimulants to the nervous system in small doses and narcotic in large doses, with the difference that they are capable of producing much more readily organic degenerative changes in the central nervous system. Fortunately, however, to do this very large amounts are required.—Ralph Stockman, *Brit. J. Hyg.*, 31: 550 (Oct.), 1931.

**Midday Meals for Preschool Children in Day Nurseries and Nursery Schools**—This is an important contribution from the U. S. Department of Agriculture giving the food value of typical nursery school menus and reci-

pes, in terms of the chemical composition of each child's portion of every dish. As the title suggests, the work is intended especially for persons responsible for feeding groups of preschool children one or two meals a day, but should be helpful in meeting the similar questions arising in hospitals and other institutions, and the question of food selection in homes where groups of young children must be fed.

In a pamphlet of 46 pages, the authors devote two-thirds of their space to a tabular showing of the chemical composition of the ingredients of recipes, in calories and in grams of protein, fat, carbohydrate, calcium, phosphorus, and iron. They include also a brief discussion of food standards for children, of factors affecting the child's food intake, such as appetite, food habits, and the mechanical problems involved in the child's manipulation and mastication of his food. Variations in the cost of menus are discussed, and examples of high and low cost menus for different months are given.—Mary E. Sweeney and Charlotte Chatfield, U. S. Dept. of Agr. *Circular 203* (Apr.), 1932.

**Polycythemia in the Rat on a Milk-Iron-Copper Diet Supplemented by Cobalt**—Thirty albino rats, 21 days old, were placed in glass cages with their mothers and fed whole milk until the 25th day. After 4 days the mothers were removed and the young rats were then placed in individual glass cages and given a basal diet of whole milk with 0.5 mg. of iron, plus 0.025 mg. of copper daily. At the end of 30 days, manganese, cobalt, nickel and zinc were added. These were fed as solutions of soluble salts and at the following levels: manganese 1.0 mg. as  $MnSO_4$ , cobalt 0.5 mg. as  $CoCl_2$ , nickel 1.0 mg. as  $NiSO_4$ , zinc 0.5 mg. as  $ZnSO_4$ . Cobalt as  $CoSO_4$ , in the amount of 0.5 mg., was fed and the results are identical with those obtained with  $CoCl_2$ .

All animals receiving the cobalt presented a striking appearance. The ears, eyes and paws became a deep red color in contrast to the pink color of the rats of the non-cobalt and normal groups. As long as cobalt was administered the polycythemia persisted. Two animals were kept polycythemic by cobalt feeding (0.5 mg. of cobalt as  $\text{CoCl}_2$  daily) for a period of 330 days.

There was only 1 fatality and that was an animal which grew well until 2 weeks before death, which occurred at 220 days of age. Hemoglobin, erythrocyte and cell volume values show a parallel rise, while the leucocyte and differential leucocyte counts show no significant alteration.—James M. Orten, F. Aline Underhill, Edward R. Mugrage and Robert C. Lewis, *J. Biol. Chem.*, 96: 11 (Apr.), 1932.

**The Iron Content of Vegetables and Fruits**—Data are given in this report on the iron content of 110 different forms, parts, or varieties of fruits and vegetables, for 82 of which some analyses were made by the author. Twelve of the 110 averages represent dried or mature plant products, and 98 refer to

fresh, succulent, or immature plant products. Four classifications were made of the 98 fruits and vegetables tested:

Group 1—13 were found to contain less than 0.00040% of iron and were considered poor sources of iron.

Group 2—44 contained 0.00040% to 0.00079% and were considered fair sources of iron.

Group 3—24 contained 0.00080% to 0.00159% and were considered good sources of iron.

Group 4—17 contained 0.00160% or more, and were considered excellent sources of iron.

The first group consisted almost entirely of fruit and fruit juices. About one-half of the second group consisted of seed pods, blanched leaves, roots and bulbs. In the third group, potatoes and thick pigmented stalks and leaves were of chief importance. In the fourth group, immature seeds of leguminous plants and thin green leaves were of importance, the latter being conspicuous for their iron value. The classification shows, as has often been observed, that much of the iron in plant tissue is associated with the chlorophyll.—Hazel K. Stiebeling, U. S. Department of Agriculture, *Circular 205* (Feb.), 1932.

# CHILD HYGIENE

## PREVENTION OF CRIPPLING IN CHILDHOOD

A REPORT of the Committee on Prevention and Research of the International Society for Crippled Children, which was presented recently at the meeting of the society at Rochester, N. Y., is of sufficient current interest to give certain excerpts in these comments.\*

Wherever, in different parts of the country, the ravages of epidemics, increases in child labor, and the onslaught of depression have been felt, an effort has been made to secure authentic information regarding the status and value of combative measures used. A study of recent literature depicting the laboratory findings of those engaged in searching out means of prevention has been made. . . .

### POLIOMYELITIS

One of the most baffling epidemics has been poliomyelitis. At times we have thought we knew something about the type of conflict this enemy would offer. But we have learned that, although its mode of attack is essentially the same, the strategy of its attacks varies. Consequently it continues to take heavy toll of children's lives and to leave many wounded and crippled upon the field. Dr. R. I. Harris of Toronto estimates that it is one of the most important causative factors of crippling, averaging 40 per cent of the cases, while tuberculosis follows with an average of 30 per cent. In the year of 1931 there were reported some 13,000 infantile paralysis cases, one-third of which occurred in New York City. . . .

Epidemiologists are of the belief that there are many more unreported cases of infantile paralysis than are reported. As in other communicable diseases, it is believed there are many mild and abortive cases. . . .

A germ that cannot be captured is extremely difficult to study. Nevertheless, what it does or does not do can be brought under observation. It has been established that one who emerges the victor after one attack is im-

mune to others. This led to the hope that the blood of such cases might help counteract the disease in other individuals, striking a spark of hope that a positive serum had been found. Recent experiments, however, have not fanned that spark into a flame as yet. Two difficulties have been met. One is to produce the serum in sufficient quantities for widespread use in the face of an epidemic, as its preparation in animals has not been perfected, and another is to discover or be apprised of the illness early enough for the serum to be effective. . . .

Treatment so far has been, for the most part, the injection of serum. At first it was believed that only the serum from convalescents could be used, and as this could not be secured in great quantity the amount to be administered was limited not only as to quantity, but as to the type of patient to receive it. . . . All the various forms of infantile paralysis can be reproduced in the monkey by injecting, under suitable conditions, extracts of the spinal cord of patients who have died of poliomyelitis. It has also been found that the serum to be used does not need to be taken from the blood of the convalescent immediately. It can be preserved in the laboratory under proper conditions for months and even a year or two without losing its effect, it has been stated.

More recently the blood of so-called normal persons has been thought to carry neutralizing substances, for the virus of infantile paralysis. Although according to Wywer, Park, and Banzhof, in the April, 1931, issue of the *Journal of Experimental Medicine*, while "Pooled serum from 'normal' adult donors has proved effective in neutralizing virus, its potency is approximately one-half that of convalescent serum." . . .

There has been a tendency to attribute to rural sections the greater prevalence of this disease. However in 1930 Ohio reported that 61 per cent of its cases were urban and 39 per cent rural. The *Weekly Bulletin* of the City of New York Department of Health for August 22, 1931, states that if the epidemic year of 1916 is excluded only a slight rural preponderance is found—not different from that of whooping cough.

Dr. Park seems inclined to view isolation as

\*A copy of the full report embodying recent bibliography may be obtained from the Cleveland Child Health Association at a cost of 5 cents.

not very valuable after the early acute stages, saying that many cases are so treated after the danger is passed. Most of us, however, would probably be inclined to agree with Dr. Parran, New York State Health Commissioner, who says, "In the absence of any better known method of combating infantile paralysis, the New York State Department of Health will continue to recommend the use of human serum unless its usefulness should be completely disproved." . . .

In Boston the Harvard Infantile Paralysis Commission, which has been functioning since 1916, was vigorously active, spotting cases and collecting serum. New York City appropriated \$75,000 emergency funds. A battalion of orthopedic nurses was concentrated in Brooklyn to care for anticipated cripples. Stations were set up to take blood from convalescents for the treatment of infantile paralysis.

At the end of the infantile paralysis season, 3 Stanford University men, Dr. Charles Egloff Clifton, Edwin William Schultz, and Louis Philipp Beghardt, announced that they had isolated and measured an organism which they were certain caused infantile paralysis. . . .

The studies of Dr. Frederick Eberson at the University of California are of interest. He has been able to segregate germs and produce a serum that checks infantile paralysis in monkeys, he reports, though he is not prepared to vouch for its success with human beings. Convalescent serum has also been collected and distributed by the Hooper Research Institute of the University of California.

Edna Foley, a member of this committee, says, "I am not sure we know any more about the prevention of poliomyelitis than we did but certainly we know a lot more about the prevention of deformity, the protection of weakened muscles, and the restoration of strength to paralyzed muscles by proper treatment." . . .

An interesting method of treatment is advocated by Dr. Henri Bórdier, of Lyon, France, consisting of the association of spinal radiotherapy and diathermy administered to the affected limbs, with the addition, where necessary, of galvanization of the atrophied muscles. Hydrotherapy, as tried in various places, is proving of value too. . . .

#### TUBERCULOSIS

Regarding tuberculosis of the bones and joints, Dr. Maxwell Harbin of Western Reserve University sounds an optimistic note, "To date there has been a steady decrease in incidence of tuberculous disease of bones and joints in childhood, although it is my impression that there has been an increase in the

incidence in adults. It would seem that the children have perhaps been protected partly by public health measures and that we are beginning to reap benefit from this source. Later, perhaps, with the letting down of public health activities, which may occur as a result of the depression, this situation may be changed."

This opinion is held by a number of other investigators throughout the country. Certainly not so many or so serious cases of tuberculous bone and joint disease are seen in the wards of our hospitals as were a decade or two ago.

Preventing young children from coming into contact with the tubercle bacilli is the best means of prevention. Inasmuch as the two sources of the bacilli are known, the matter of prevention may appear, superficially, to be a fairly easy one. The human source is the most common one, and in many respects the most difficult to find and handle; the bovine source, which is responsible in some places, it is estimated, for between 10 and 15 per cent of the tuberculous joints and bones, should be watched more carefully. General pasteurization of milk supply eradicates a large percentage of this danger. But pasteurization is only adequately accomplished, as a rule, in large centers. In smaller towns and rural sections of the country there is more danger from bovine tuberculosis. The eradication of bovine tuberculosis has been aided by the combined efforts of federal and state governments until a decrease in the per cent of cattle reacting to tuberculin has decreased by more than half in the past 15 years. Nevertheless, it is still estimated that in cases of children under 5 years of age, suffering from tuberculosis, 21 per cent are caused by the bovine type of infection; in cases between the ages of 5 and 16 years, 26 per cent are of this type. . . .

It is recognized that other communicable diseases may account for some of the crippling, but these bear a very small proportion of the total. Syphilis now comes under surveillance earlier than formerly and is more intensively treated. Diphtheritic paralyses are gradually fading out of the picture due to the exact knowledge we have of this disease as to cause, prevention, and cure.

#### CEREBRAL PALSIES AND BIRTH INJURIES

While there is some scattered experimentation of promising value going on at present for the prevention of cerebral palsies and birth injuries, little of note has appeared concerning these subjects the past year. Dr. Maxwell Harbin says, "The prevention of Erb's and Erb-Duchenne's palsies lies largely

in the realm of the obstetrician who delivers the child. Certainly with the exercise of due care a tremendous number of these injuries may be avoided. Therefore, it would seem that propaganda relating to the obstetrician is most important. It should be emphasized in the teaching of medical students as well as the instruction of internes in hospitals where there is an obstetrical service." Full consideration to this phase of the subject is given in the White House Conference on Child Health and Protection reports. Dr. Harbin says further, "Recognition of the presence of a contracted pelvis in the female before birth is of tremendous importance in prevention, as well as the very careful supervision by the obstetrician of the female primipara during pregnancy and labor. Even with close observation it is next to impossible to differentiate between cerebral damage resulting from actual laceration of the brain tissue and damage resulting from pressure by hemorrhage. It is possible that early craniotomy may result in some relief from the latter class although it has seemed impracticable and has not been practised to any extent to date."

Dr. Helen MacMurchy believes, "It would seem that the chief means of prevention of these injuries is in better obstetrics and in the better education of the public. Medical students in their undergraduate courses and medical practitioners in postgraduate courses need more satisfactory instruction, especially in regard to the dangers of instrumental interference. The general public needs education in regard to the danger of instrumental interference and the danger of pressing on the medical attendant, against his own better judgment, injudicious means to hasten the occurrence of birth."

Dr. E. C. Hartley thinks that while the question of birth injuries "may be met in part by better obstetrical care, there is still a background of which at present we know nothing, but which must be understood in order to make any great impression upon the incidence of birth injuries." He refers to "a peculiar susceptibility which some children appear to have for injury at birth," into which he believes "some constitutional or other factor enters to render some children more liable to birth injury than others." . . .

Dr. Fred L. Adair has been studying the subject of obstetrical birth injuries, in Chicago, and at Harvard, Bronson Crothers has been interesting himself in the neurological aspects of such injuries. Neither of them has completed his work, but the quality and extent of their investigations promise much for future preventive methods.

#### RICKETS AND NUTRITIONAL DISORDERS

Deformities from rickets are among the most common and, at the same time, the most needless of any known. That the present period will see an increase in this type of crippling seems not at all improbable, although education has increased widely the use of protective means up to this time. At one health center in New York City, where the per cent of undernourished children has been carefully diagnosed during the past 3 years, it is reported that malnutrition has increased from 18 per cent to 60 per cent since 1928. Public health nurses report that their work is handicapped because parents cannot provide their children with the diet recommended. In Louisville, Ky., one agency reports a decrease of 1,000 in the number of children able to meet the health and weight standards . . . Any extensive data regarding conditions arising from malnutrition cannot be secured at present, and perhaps it will be difficult to do so at the close of the present economic period. There can be little question, however, regarding the findings of school examiners, pediatricians and general practitioners in this respect during the coming years.

Methods of preventing rickets have been under investigation since Glisson's work on etiology in 1650; Mellanby's work in 1918 on antirachitic factor or vitamin was followed by the demonstration of Huldshinsky in 1919 of the curative value of ultraviolet rays of the mercury vapor quartz lamp. The preventive and curative value of this treatment has also been thoroughly proved by Gerstenberger, and others. Hess and Unger made the observation in 1921 that sunshine has a similar action on rickets; the following year McCollum, Simonds, Becker and Shipley proved the existence of vitamin D and that cod liver oil was its most concentrated source. Next came the discovery that food containing cholesterol or allied substances could be activated by ultraviolet rays and given antirachitic property. . . .

Unobstructed sunshine is the cheapest and most effective of any of the elements discovered. But in smoky, foggy cities the alternative is diet control and the use of potent cod liver oil. The ingestion of a diet rich in calcium, phosphorus and vitamin D usually results in a definite change within a period of from 10 days to 2 weeks. The ultraviolet lamps on the market should be used with caution and under the direction and supervision of a physician. . . .

#### CHILD LABOR

The Committee on Education and Training

of the White House Conference learned that, "Although 15 states and the District of Columbia apply the minimum age provisions to all gainful employment, and 28 to a more or less comprehensive list of employments, 5 set no minimum age except for employment in factories and certain dangerous or hazardous occupations, and 2, none except for certain dangerous and hazardous occupations. The various kinds of domestic and personal service, agricultural work and factory work in the home are usually unregulated by child labor laws. In some states canneries are exempt from the operation of the child labor law. . . ."

Agricultural occupations are the most difficult to regulate. While many agricultural tasks are light enough for children, they are often kept at them for periods of anywhere from 8 to 12 hours at a time. Certain types of farm work involve cramped positions for the workers, exposure to dampness and cold, and danger in the use of machinery. Furthermore, there are the migratory farm workers, who travel from place to place, following the crops and seasons, whose living conditions are usually bad, being often unsanitary labor camps. . . .

Inasmuch as child labor is considered to be largely forced by another of the child's enemies, poverty, it is not improbable that an increase of illegal employment of children is occurring at present. In so far as it is possible to bring about a solution of the problems of adult employment, unemployment insurance, and other matters concerned with establishing decent standards of living, general progress toward a reduction of child labor will be made. It is the recommendation of the committee that those concerned with child welfare bear this in mind. On the other hand, many children who have left school to become employed are unable to find work at present, and a more careful observance of school attendance laws will no doubt return many of them to school. . . .

Another suggestion the committee would make is that statistics of injuries to minors be kept more accurately, and separately from other figures, in order that comparable facts may be presented to a public that should be well informed. Most of all, the committee is in agreement with the findings of the White House Conference, that a national minimum standard regulating the employment of minors should be established in order to eliminate the

inequalities and injustices existing between the differing laws of the states.

#### ACCIDENTS

Safety campaigns have been in evidence for some time. The greatest efforts have been directed toward schools, for it is there that the child is most available and open to all kinds of education. In 1931 a *Guide Book for Safety Education*, with a foreword by William John Cooper, U. S. Commissioner of Education, was published with the aim of offering school children, from the kindergarten up, interesting educational material on safety. In larger cities school patrols have become a part of the regular policing function, and in some rural communities they are coming into use.

In spite of the precautions taken, statistics from many parts of the country reveal that the highest average of accidents in any age group is found among children under 16 in trade, and next, among accident-causes, automobiles and other motor vehicles have the highest severity. Machinery has caused the greatest number of accidents it is reported in Illinois, and also in Ohio, among employed minors the past year. The Metropolitan Life Insurance Company states in its *Bulletin* of October, 1930, that of automobile accidents involving 100,027 pedestrians 17 per cent were children struck at play in the streets. . . .

Although a survey, during 1931, of the efforts to prevent crippling in children is both enlightening and encouraging, it does not fail to warn that such advancement as has been made has been at the expense of continual vigilance. The mighty arm of progress must strike here and there at ignorance, carelessness, thoughtlessness, if the day is to be won for the child.

While the report is confined largely to crippling viewed as physical disability of the trunk and limbs, the committee is fully aware that it has much wider implications. Crippling in its widest sense should include children who are seriously malnourished, partially or wholly blind or deaf, and those who have major deformities of the lips, jaws, or teeth. To these might well be added the cardiac cases and those suffering from pulmonary tuberculosis. All of these, however, are considered in detail by other national and local organizations, and much worthwhile literature is available regarding the extent, causes, prevention and cure of disabling conditions.

National Biennial Nursing Convention—Even the weather did its best to make the joint biennial convention of the American Nurses' Association, the National Organization for Public Health Nursing, and the National League for Nursing Education, held in San Antonio, Tex., April 11–15, one of the pleasantest as well as one of the most profitable conventions these groups have held. Over 2,600 members and delegates of the three organizations were adequately and comfortably accommodated in San Antonio's spacious new Auditorium, where general meetings were held, and

in its interesting and efficient hotels for special group meetings. The exhibits were particularly well planned from the standpoint of service and educational value.

The alleviation and prevention of the serious unemployment with which the nursing profession is faced was the great concern of this convention. The profession will continue to face a serious situation even in normal times due to the annual graduation of many thousands of nurses each year who are not needed. There is now, according to Dr. May Ayres Burgess, 1 nurse to every 63 families in the United States. The question was discussed from many angles, bringing out three suggestions for remedies: the limiting of the out-

\* The printed matter of other material relating to public health nursing to Eva P. MacDougall, 6 State House Annex, Indianapolis, Ind.

put of nursing schools, the more careful selection of students for the nursing school and the distribution of various kinds of nursing service to meet the needs.

The members of the National Organization for Public Health Nursing are particularly concerned with the training of nurses for public health nursing and their continuous education to meet the ever changing, ever developing demands of the field in which they are working. Do results justify the expense of our staff education programs? Can we maintain the present program? Are organizations assuming responsibility in public health nursing education which should be assumed by the individual nurse? These, according to Ellen Buell, Director of the Department of Public Health Nursing, Syracuse University, are pertinent questions at a time when all community supported projects are being scrutinized as never before.

Much emphasis was placed on the utilization of the help lay people could give us as volunteer workers, board and committee members, and advisory counsel members for both official and non-official agencies, hospitals, nurses' registries, and nursing schools.

The highlight of the convention was the most impressive service in which Anne W. Goodrich, Dean of the Yale School of Nursing, was awarded, to the great delight of everyone interested in nursing, the Saunders' Medal for distinguished service to nursing.

One could scarcely help feeling throughout the whole convention the stress put on maintaining, in some ways perhaps regaining, that true spirit of nursing which has made it respected and appreciated through the ages.

Certainly no meeting has been more effectively handled than this one. The Texas sunshine, beautiful flowers, the unlimited hospitality of the Southwest, and the well planned and pertinent program made this convention one not to be

forgotten for its delight, inspiration and help.

By majority vote of the delegates the next biennial convention will be held in Washington, D. C., in 1934. V. A. J.

**A Parochial School Health Bureau**—In most of the large cities in the United States the boards of health provide for medical inspection and follow-up of parochial school children—and public and parochial school children receive the same attention and care. Often in rural and semi-rural communities medical and nursing service is given under the jurisdiction of the state board of health either by direct service or through county health units, in which case all children are served alike. In St. Louis the Board of Education and not the Health Department finances the medical inspection in the public schools, and in order to have this service the 104 Catholic parochial schools in city and county have to finance it themselves.

At first, health work in the parochial schools of St. Louis was conducted by volunteer agencies. St. Louis University provided speakers, the Tuberculosis Association promoted classroom health education, and Catholic women's organizations coöperated and aided in these activities. This arrangement brought results, but there was a lack of unity, and finally a Catholic School Health Bureau was formed with representatives from all these agencies on it. The Catholic women's clubs raised the necessary funds and the Superintendent of the parochial schools and the St. Louis University School of Medicine supervised the health program. This bureau, organized in September, 1927, was the first one of its kind in the United States. It was located at the St. Louis University School of Medicine, which gave it not only a central, convenient point from which to work, but also prestige.

A modern complete school health pro-

gram as we know it today was soon outlined and started. The staff consisted of a director, 4 physicians, 2 public health nurses, and 1 office secretary. A little later a social worker was added through the interest of the Daughters of Isabella, a local Catholic women's organization.

In addition to routine medical inspections and follow-up, health institutes for the teaching sisters were arranged and classes in school hygiene, health education, and care of the problem child were held in St. Louis University for parochial school teachers. For these the sisters and teachers received scholastic credit.

A course of study in health for the parochial schools is in process of being written by a committee of sisters in co-operation with the St. Louis University School of Education and the Catholic School Health Bureau.

The bureau has worked very closely

with the St. Louis Health Department in communicable disease control. It has carried on a continuous research service also, to ascertain the trend in physical defects and learn the relation between schools, neighborhoods, and racial groups. One survey was made to learn what other Catholic communities are doing for handicapped children in parochial schools, and another to study health knowledge versus health habits of children under the supervision of the bureau. A Children's Dental Clinic for parochial school children was established by the St. Louis University School of Dentistry which has been very successful.

The 4 years the St. Louis Catholic School Health Bureau has been functioning have proved the soundness of its organization and value of its work.—Harvey Smith, *Health Work in St. Louis Parochial Schools*, *Pub. Health Nurs.*, XXIV, 4: 210-212 (Apr.), 1932.

# EDUCATION AND PUBLICITY\*

**Two Days of Intensive Study—**Plans are being completed for a Public Health Education Institute to be held immediately preceding the Annual Meeting in Washington in October. Details will be announced next month.

**Health Publicity Awards For 1931-1932—**As announced May 15, public health claimed 4 of the 10 citations for publicity of unusual merit as selected by the Social Work Publicity Council. A committee of 5 met monthly to review the specimens received. The citations for public health material appear below.

The Awards Committee cites for exceptional merit **HEALTH OFFICER'S REPORT, MIDDLETOWN, N. Y.:**

*Because*, prepared with the will-to-be-read, it entices laymen into its net as readers, in addition to public health workers.

*Because* it shows a mastery of mimeographing technic and proves that good taste and effectiveness are not dependent on expensive materials and formality. The illustrations and decorations are deftly done and supply the touch of humor which leavens the whole report. The tailpiece is delightful and the gesture gracious that the able mimeographer has been given the opportunity to sign her work.

*Because* the text is simple, direct and has a sufficiently informal air to hold the interest its appearance has attracted. Public health workers will find the report of activities substantial in spite of its informality. They may miss, however, information on the size of the community, the size of the staff and organization, and the cost of the health program, helpful facts to have in such a report.

The welfare section of the report is headed with a verse,

"To cure myself a great dislike,  
Of little trials life brings,  
I simply call a halt and take  
A different view of things."

While the dramatic illustration shows that this refers to the preschool child's attitude toward spinach, it is exactly what the author has done in approaching the usually considered gloomy task of getting the year's work down on paper. He has taken a different view of annual reports.

The Awards Committee cites for exceptional merit "Two TUBS OF 'CHINY ASTIES'" by Lucretia Penny, Published in *Hygeia*, February, 1932:

*Because* it shows by the short cut of a delightful story the variety of services crammed into the day's work of a county nurse.

*Because* all this knowledge can be gained in about 6 minutes of reading time, and the subtle interplay between nurse and client is told with well sustained implication.

*Because* the young mountain mother, her baby who is the patient, and her stepmother, Miss 'Talithy are flesh and blood. It all sounds real, from the sound of the paling gate swung back into place by a rusty plow point, to the nurse's understanding of the starved lives of tenant farmers.

*Because* the nurse is shown in her frequent rôle of interpreter of two opposing points of view. In this case a family conflict over some "chiny asties" was depriving the delicate 2-year-old girl of milk from her grandfather's cow. Without taking sides and without apparent efforts to referee, she casually plants seeds of the understanding which later brings the factions together.

*Because* even the nurse's victory is most disarmingly recorded, just a swift glimpse of the reunited grown-ups on the stepmother's porch, and the little girl bending demurely over the asters, her hands behind her back, as the nurse drives past the cabin on her way home.

(Lucretia Penny is a pseudonym. The author, who is a frequent contributor to *Hygeia*, gained her knowledge of rural communities

\* Please address questions, samples of printed matter, criticisms of anything which appears herein, etc., to Evart G. Routzahn, 130 E. 22d St., New York, N. Y.

from living in them, and of the people who live and struggle in them from doing family case work in Tennessee and Kentucky. A friend who was a public health nurse gave her the insight into nursing problems.)

The Awards Committee cites for exceptional merit THE 1932 EARLY DIAGNOSIS CAMPAIGN OF THE NATIONAL TUBERCULOSIS ASSOCIATION:

*Because* with an event of importance to live up to, the fiftieth anniversary of Robert Koch's announcement of his discovery of the tubercle bacillus, this year's Early Diagnosis Campaign makes history in our field of getting messages over. First of all, it has made good use of the anniversary day, March 24, to introduce its April campaign by newspaper articles of vivid interest.

The publicity kit contained informative material adaptable to all sorts of original plans that showed good team work between national and local associations. Iowa, for instance, localized the Koch story by featuring the doctor's visit to relatives in a little Iowa town, re-using the photographs which appeared at that time in the *Journal of the State Medical Society*.

*Because*, while the general plan of the campaign is highly praiseworthy for its focusing so intently on the fact that "Tuberculosis Causes Tuberculosis—Every Case Comes from Another," it has an even better point in its favor. The committee feels that the kernel of the campaign's excellence lies in 4 booklets, each written for a special group.

"Closing In On the Old Enemy" is for the health officer; "Where Is the Other Case?" for the physician; "The Adventure of Case Finding" for the public health nurse; and "Why Does It Run in the Family?" for the social worker. Having realized the importance of supplying diversified information to these powerful, highly specialized allies, the association has given them usable material. The booklets, about 10 pages each, are well printed in a conservative but pleasing form which suggests reference material rather than campaign literature.

*Because*, although the leaflet for distribution to the general public, "Tuberculosis Doesn't Just Happen," falls below the 4 professional booklets in quality, other features of the campaign for use on screen, radio, platform, and display approach them in value. The window poster, for instance, with its big and little cog wheels method to convey the inter-relationship between old and new cases of tuberculosis, has the poster prerequisites of good design, simplicity and speed of expression.

The Awards Committee cites for exceptional merit SOLVING THE NURSING PROBLEM IN MILWAUKEE, A Series of Ten Feature Stories in the *Milwaukee Journal*:

*Because* they tell a readable, comprehensive story in true newspaper style. Considering how factual the articles are, attempting to cover thoroughly all divisions of visiting nurse service, they are popular enough to attract casual page combers. Yet in being popular they have not depended at all on the romantic "angel of mercy" halo with which writers often crown the nurse.

*Because* the articles have a well thought out plan. Variety has been captured by telling each story from a different angle—one from the observing eyes of the student nurse who sees for the first time the resourcefulness of "old hands at district nursing" as they improvise household makeshifts in lieu of the complete equipment always at hand in a hospital.

Another article is built on the mystery of "What is in the nurse's black bag?" and on the magic of her skill in packing and repacking its numerous and fragile contents.

*Because* the leads are good, the first being a complete summary of the articles, "A nurse for an hour, a nurse who will skilfully bathe a convalescent, dress a wound, give a refreshing massage, prepare the new baby's formula, or do any other of the numerous things required by a patient in the home who needs expert care at minimum cost is the valuable general service offered by the Visiting Nurse Association."

The second lead, "Eighty-five per cent of the people sick in Milwaukee County are sick at home," stimulates interest in an article on the training of nurses.

*Because* the illustrations and their captions are a real part of the story. Although the captions are written in a decidedly untabloid style, they do make sure that a reader who glances only at the pictures and their titles will get an outline impression of the services of the Visiting Nurse Association.

**War Against Bacteria Dramatized**—Some of the adventure, mystery, and excitement of scientific search among the bacteria is given to that kaleidoscopic group known as the radio audience, in a series of 13 radio plays, "The Drama of Science." The Detroit Department of Health presented the series

under the sponsorship of the Detroit Dairy and Food Council. Written by Rex White, a newspaper man and writer of short plays, they were acted by a professional group, the Detroit Players. A smithy anvil, the howls of mad wolves, the horrors of a primitive war hospital, the sounds on a Viking ship at sea, everything, indeed, except the death rattle of the bacteria placed on "the spot," is included in the "sound" effects accompanying the voices.

If there is some over-sentimentalizing of the material, it may be because the planners measured shrewdly the over-sentimentality of the public mind. And in the same way if, along with the convincing emphasis on courage and sacrifice, there was too much thought of the fame that was to come, it may have been a concession to our success-adoring public.

High points in the dramatization include two scenes in the Louis Pasteur episode, 50 years apart:

*Louis*—I am not afraid, father. (Howl nearer)

*Past.*—Afraid or not—get in. Smith, swing that great door closed.

*Smith*—Aye. I wish you had your musket, Neighbor Pasteur. (Door shuts—howl nearer)

*Past.*—It comes nearer. I swear it's the mad wolf and he's hopping along the highway. He'll run straight along its length and good God protect those who venture in his path. (Howl much nearer)

*Louis*—Look, father, there he comes. See—by Monsieur the Notary's house.

*Smith*—It's so. Here, Jules, give me that hammer. Pasteur, take the scythe just in case he veers toward the smithy door. (Howls)

*Louis*—Oh, father—see. Nicol the peasant. He is filled with wine and he is staggering into the road. Go back, Nicol, go back.

*Smith*—Back, you drunken fool. (Howls—Barks)

*Past.*—Do not look, son, do not look.

*Louis*—I must, father. See, there is the landlord of the inn. He has his pistol.

...

*Louis*—Father—father. What are they going to do?

*Past.*—The smith will press the white hot iron to the wounds. It is the only hope. Perhaps if he is quick enough he can burn the poisons.

...

*Past.*—Aye. It is white hot. Here are the pinchers, Smith. (Clank of iron)

...

*Smith*—Hold him men—tightly. Don't let him move. The arm first. (Hiss of iron—scream of pain)

...

And 50 years later, in Pasteur's laboratory:

*Roux*—He is the most vicious of all, master.

*Past.*—Aye, he looks it. His eyes are all but lost in the crimson curtain of their inflammation.

*Roux*—The poison must be rich in that great throat.

...

*Past.*—Wrap your arms with cloth and wear these gloves.

*Roux*—But you, master.

*Past.*—I cannot have my hands made awkward with gloves. I'll need all my finger skill. Roux—raise the gate. I will catch him by the throat.

*Roux*—Are you sure, master—sure you will not miss? If you do—we all must die.

*Past.*—Hush—timid one. I will not fail.

...

*Roux*—Are you going to swab the throat? I see no instruments.

*Past.*—I have—this.

*Roux*—That? Why that is but a glass tube.

*Past.*—Aye—it will do.

*Roux*—But—but—it has no scraping surface.

*Past.*—No. But it has a hollow stem.

*Roux*—Master, master, not that. You—you are not going to—to—

*Past.*—After I have him out, you and Chamberland will hold him and force his jaws apart—wide. You understand? Then I will place the tube into his throat and—draw up the virus.

*Roux*—Mon Dieu. Master. It is madness. Suppose you miscalculate. One tiny drop of that stuff in your throat—one tiny drop and—

*Past.*—Hush. Up with the gate. I order you. (Gate draws up—dog snarls—hoarse barks—choking noises)

How colorfully the whole series is done is shown by the different atmosphere in this glimpse of Dr. Jenner's smallpox vaccination experiments:

*Jenner*—So hast never had a shilling of thy own, boy?

*Boy*—No, sir. I had tuppence once, doctor. 'Twas fair day and I bought me taffy and great baked potato adrip wi' butter and salt.

*Jenner*—Art a brave boy, James?

*Boy*—I know not. I am not afeered of Farmer Knowle's black Hereford bull which doth chase the other children—and once, you will remember you did set my arm.

*Jenner*—Aye—broke stealing apples, as I also remember. It was because you let never a cry from your lips that I have chosen you today. Your father and mother hath given consent.

*Boy*—Art going to hurt me?

*Jenner*—Nay—no more than the prick of a pin. See—I will take this little knife and make a very small dot in thy arm—no more than you would get sliding down a tree—or dropping into a blackthorn. And I will give thee a shilling for thy very own. To waste in any manner of gauds you wish. Or to fill that small belly of thine with toffee and ginger beer.

...

*Jenner*—Sarah, my girl—hath the water boiled on the hob?

*Maid*—Yes. The kettle has been singing fair loud these 5 minutes.

*Lady Dorothea*—What are you going to do?

*Jenner*—I am going to inoculate the lad with the virus of cowpox—from the hand of Sarah. And 6 weeks from now I will inoculate the same boy with smallpox virus.

*Lady D*—Inoculate? You mean put the poison of the pox into his blood?

*Jenner*—Exactly. I have found by careful study that those who have the cowpox—a minor ailment—never get the smallpox. Why? I do not know. But with this boy I am going to prove my knowledge. . . .

Among the episodes besides the findings of Pasteur are the discovery by Roux, his pupil, of the diphtheria anti-toxin; by Lister, of the safety of surgery; Florence Nightingale fighting not only sepsis in neglected wounds, but the stupidity of the War Department; and the closing down on the yellow fever mosquito by Reed and Carroll.

In each episode there is just enough continuity to connect the drama with our own lives of today, and the last of the series dramatizes a diphtheria experience which had recently occurred in Detroit.—Hilary Campbell.

We plan to follow the above review, from a non-health worker, by comments from several in the field of health. They will discuss the factual material as well as the dramatic setting of these dramatizations.

Copies of the Radiodramas will be supplied upon request to Dr. Henry C. Vaughan, Department of Health, Detroit. Comment should be sent to editor of this department.

## BOOKS AND REPORTS

**A Doctor of the 1870's and 80's—By William Allen Pusey.** Springfield, Ill.: Charles C. Thomas, 1932. Price, \$3.00.

The name of William Allen Pusey as author of any book would attract attention. He has now given us the story of his father's life and practice in a small town in middle Kentucky. He was the old-time country doctor, going over roads in the old fashioned buggy or on horseback in every sort of weather. All persons, regardless of their circumstances, received the same conscientious and kindly attention. Though the surroundings described are widely different, one is constantly reminded of "A Doctor of the Old School."

Dr. Pusey has given a worthy tribute to a loved parent from whom he gained much and to whom he owed much. For the general reader, perhaps the most interesting part of the book is Chapter X, entitled "Appraisal," in which the author discusses the question as to whether those who, like his father, stick to the country in spite of all of its hardships, or the physician of the present day who practises in a city with companionship and all conveniences and assistance constantly at hand get the most out of life. In the following words he sums up the advantages and disadvantages, and concludes in favor of the country doctor:

Things of the sort I have tried to indicate were the compensations for the hardships of the country doctor's life, as Pusey lived it—the satisfactions of a life of useful service, and, as a result of that, economic and spiritual independence and the gratitude and esteem and affection of those he served. A man can hardly hope for more in this world. If he can gain these in an occupation that is in-

teresting and stimulating, that keeps him in the open, that gives him an opportunity for close and abundant association with his family, he has about as much as life offers; and all these Pusey had. The balance in favor of such a life, I should say, is large.

In those who have lived such a life or who have come into contact with such a man, the book will touch a most responsive chord. To the younger practitioners who must have tiled floors, beautiful nurses, and an abundance of dressings, towels and expensive paraphernalia of all sorts even to open a boil, we especially recommend the book as a picture of the type of men who made American medicine.

MAZŮCK P. RAVENEL

**Official and Tentative Methods of Analysis of the Association of Official Agricultural Chemists.** (3d ed.) Washington: Association of Official Agricultural Chemists, 1931. 593 pp. Price, \$5.00.

For the past 10 years public health laboratories have relied on these methods in connection with chemical analyses of foods and drugs. To what extent this work, aside from that necessary for control of dairy products, is properly a function of a public health laboratory, may be seriously questioned, but when such analyses are made it is just as necessary for a public health laboratory to follow recognized "official" methods as it is for the state or government regulatory laboratory. This third edition is very welcome to all concerned.

It would be absurd to attempt a detailed review of a book containing hundreds of methods of analysis. Revisions of old methods and approval of new

ones are made by the association sponsoring these procedures, only after a reasonable amount of publicity. Hence, those chemists most concerned already have been informed of prospective changes. Laboratory workers will await with interest the projected methods involving such subjects as vitamins and bacteriological procedures. The compilers are to be congratulated on the indexing and reference numbers, which will be appreciated by the very large number of chemists who use the book.

JOHN F. NORTON

**Nursing Education: A Survey of Day Nurseries, Nursery Schools, Private Kindergartens in the United States—By John E. Anderson, Ph.D.** *A publication of the White House Conference on Child Health and Protection.* New York: Century, 1931. Price, \$2.00.

This volume is based upon an extensive study of schedules from 1,275 institutions caring for the preschool child in which a total of 49,358 children were enrolled, and upon a study of 2,757 families with over 4,000 children.

The Committee on Education and Training of Infant and Preschool Children had two main projects: (1) A survey of institutions for the education and training of young children, and (2) The study of young children in the home. Only the first of these is considered in this volume.

The report covers the most comprehensive survey of day nurseries, nursery schools, and private kindergartens ever carried out in this country. These institutions are the ones in our country having the largest contact with preschool children.

We have long known a great deal about the infant and the child of school age, but it has been very difficult to secure authentic information regarding the preschool children of whom there are over sixteen million in the United

States. The present survey will help us to evaluate better the functions of the preschool child agencies and their place in modern society.

The book opens with a historical résumé of organized care for young children, and discusses briefly the various types of institutions.

The method of obtaining data is described, and a detailed classification as to type and geographical location given. Typical and selected institutions are discussed. This is followed by a very informative chapter on auspices, support, tuition, and purposes.

Another chapter deals with the number of children cared for in any one institution, sessions, and attendance.

Of special interest to the health officer is the chapter on medical facilities which includes medical inspection, physical and dental examinations, vaccination, immunization, diet, dietitians, etc.

The educational facilities and program receive considerable attention.

Specific recommendations are given, as well as general findings. The appendix contains a copy of the questionnaire used in the study and a geographical list of the contributing institutions.

The same high quality of printing is maintained as in all other publications of the White House Conference.

RICHARD A. BOLT

**Diphtherieepidemien der letzten Jahre, das Heilserum und die Schutzimpfung—By E. Friedberger.** *Aus dem Forschungsinstitut für Hygiene und Immunitätslehre, Berlin-Dahlem.* Berlin and Vienna: Urban and Schwarzenberg, 1931. 50 pp., 56 figs.

Dr. Friedberger, in his monograph on diphtheria epidemicity, has made use of interesting data both statistical and experimental. His work is not so much a criticism of present-day methods for the control and prevention of this dis-

ease as a plea for more careful study of these methods, keeping in mind the fact that all infectious diseases move normally in cycles and that disease and population composition mutually affect each other.

He states that diphtheria is a disease which experiences periods of great dissemination which alternate with periods of almost complete disappearance. It reached its height in Central Europe about the middle of the 80's and then fell with remissions until after the Great War. The decrease, especially since the beginning of the 90's, has been attributed to the introduction of antitoxin without considering the normal decline.

Behring gave to the medical world the idea of active immunization but it was in the United States that this was worked out with great energy and vigor. It appears that since then diphtheria has diminished considerably in America while in Germany it has greatly increased. It is impossible, however, to conclude that this decrease was due to the measure of control alone. Since 1924, both in the old and new worlds, the idea of diphtheria prophylaxis and therapeusis has become so firmly established that the following relationships seem apparent: the United States with much protective immunization has little diphtheria while Europe with little protective immunization has a great deal.

If these associations are based on cause and effect, immunization should be practised in Europe and diphtheria should then decrease as in America. Differences in economic conditions in the two hemispheres during the last 20 years must be considered before this assumption may be made. Gottstein pointed out the fact that antitoxin was first employed during the descending phase of a natural wave of diphtheria incidence. He was able also to explain fluctuations on the basis of increased natural immunization because of latent infection of alternate generations. He

asserted that the real test of diphtheria prophylaxis and therapy would come when the infection again began to ascend naturally.

Morbidity and mortality have increased greatly in Germany but the fatality rate has decreased. The increase of diphtheria is not as yet in the nature of a general epidemic but is localized in certain focuses, Berlin, Rhineland-Westphalia, Koenigsberg, Breslau, etc. The focuses are well scattered and the mortality is highest in large cities. In Leipzig (1910) and in Hamburg (1911) similar focuses occurred. The failure of serum treatment at that time was said to have been because of the low unit value, insufficient doses, and delayed administration. The same failure is being observed at the present time when these explanations do not hold.

Friedberger closes with the statement that because of the great concentration on the theoretical aspects of serum therapy there has been an unwarranted application of laboratory results to human experience. By the collection of epidemiological data concerning diphtheria incidence, therapy, and protective immunization, new avenues of approach to control measures against diphtheria should be made possible.

E. L. LUCIA

#### Gynecology and Urology for Nurses

—By Dr. Samuel S. Rosenfeld. New York: Wood, 1931. 230 pp. Price, \$2.00.

At the National League of Nursing Education in Atlanta, 1931, Dr. May Ayres Burgess made a plea for simpler nursing textbooks. This seems to be one of the strong points in Dr. S. S. Rosenfeld's new book.

The first three chapters cover briefly and concisely the anatomy, physiology and pathological conditions of the female genital tract. These serve as a good background for the procedures,

medical and surgical, which are covered next.

The illustrations are clear-cut and not so numerous as to be confusing.

Operative procedures described are the ones most commonly met, and the student is not bewildered by a multitude of variations.

The chapter on Urology might be considered a bit too brief. The pathological conditions are clearly described, but the operative measures will need to be supplemented by well planned lectures.

On the whole, the textbook should prove valuable for use during the course of gynecology and urology, and also as a worthwhile addition to the reference library.

JESSIE L. GROVES

*Essays on Marriage—By Frederick M. Harris. New York: Association Press, 1931. 208 pp. Price, \$2.00.*

The late Frederick Harris, of the national staff of the Young Men's Christian Association, left unfinished manuscripts which the editor, Professor Harrison S. Elliott, has arranged in ten very interesting and thought provoking essays regarding present-day problems of marriage.

The chapters deal with the present status and attitudes, marriage customs, marriage a partnership, conjugal affection and sexual desire, results of ignorance and silence, choice of a mate, and limitation of families. The book will be useful to discriminating advisers and counsellors who deal with personal problems in the matrimonial field and to critical readers who are advanced in their studies in family sociology; but for the rank and file of general readers who need some guidance in preparation for marriage, these essays will suggest more problems than they will solve.

Note that the book is recommended to "discriminating" counsellors and "critical" students. This is so because the essays are, in spots, uncritical

and unscientific, certain authors quoted are not worth the space, some advice given is highly debatable, and many good points get lost in a wilderness of words. In short, the book as a whole is not for the beginner in matrimonial literature, but interesting and stimulating for one who already knows enough to pick and choose the paragraphs where the author is on solid ground.

M. A. BIGELOW

*The Essentials of Swimming Pool Sanitation—By C. A. Scott, P.B.E. Chicago: Published by Author, 1931. 126 pp. Price, \$1.00.*

Swimming pool managers, public health officials, and others having to do with the operation of swimming pools have long felt the need of a book to which they could turn for information when they were in doubt as to some question of sanitary practice. This need the author has attempted to supply by telling in his own language some of the facts and principles which have been hidden in the various reports of the Joint Committee on Bathing Places of the Conference of State Sanitary Engineers and the Public Health Engineering Section of the American Public Health Association.

After a short homily on the passing of the old swimming hole and its replacement by the modern swimming pool with its complicated equipment for purification and disinfection, the author proceeds with discussions of the bacteriology of swimming pool water and of the methods for making bacteriological examinations and their significance. The bacteriological procedures recommended generally follow the *Standard Methods for Water Analysis*. There are, however, some discrepancies, as, for example, in the use of dextrose broth for making fermentation tests which was discarded as standard practice some 20 years ago. The erroneous statement that the standard limits for

numbers of bacteria in pool waters are the same for counts made on agar plates incubated at room temperature and at body temperature can probably be attributed to careless proof reading.

The real meat of the book is contained in 3 chapters: Removal of Objectionable Matter, The Filter and Its Operation, and Sterilizing the Water, in which the different types of apparatus for cleaning the pool, and the equipment for keeping the water clean and safe are described and their operation is outlined.

Suggestions are given for the care of the floor and walls of natatoriums. A schedule is outlined covering the operator's daily routine for cleaning the pool, inspection and maintenance of the filter and sterilizing equipment, and for making the necessary chemical tests of the water, for which the methods are described fully. A section on trouble shooting should be very helpful to the operator whose filtration system fails for some unknown reason to function properly. The directions for first aid treatment for chlorine exposure are also useful although the probability that they may be needed is rather remote.

In his discussion of methods for sterilizing the water the author takes issue with the Joint Committee on Bathing Places for their failure to approve other methods than chlorination, and presents in some detail the advantages claimed by manufacturers of ultraviolet ray and ozone equipment.

The final chapter treats of the methods for submerged lighting of pools, a subject which is just beginning to come into prominence. Notes at the end of the book contain miscellaneous information on the requirements for pool marking for swimming meets, official dimensions and height of spring boards, etc., which will help the owners in making the pool useful to the public.

Unfortunately there is a lack of coordination in the arrangement of the subject matter, in numerous cases im-

portant topics being introduced into the discussion of unrelated subjects. In the absence of either a table of contents or an index this makes difficult the use of this book as a handbook or work of reference, which is its stated purpose. Nevertheless it fills a gap in the literature of public sanitation which has long been conspicuous and should therefore find a ready welcome by public health officials as well as those who own and operate swimming pools.

STEPHEN DEM. GAGE

**Cancer and Race: A Study of the Incidence of Cancer Among Jews**  
—By Maurice Sorsby. New York: Wood, 1931. 120 pp. Price, \$3.00.

Dr. Sorsby has produced one of the most interesting books on cancer which have appeared for a long time. In spite of the fact that its scope is limited to a statistical study of the incidence of cancer among Jews as compared with the incidence among others living in the same environment, and to a consideration of the factors which may account for the differences found, the volume is one which no serious student of the prevalence of cancer can afford to be without. It is the outcome of a paper which the author read at the international conference on cancer in London, 1928, in which the comparative freedom of Jewish women from cancer of the uterus was attributed to their habits of sexual hygiene.

In this book the author sets out to see, first, whether there is any material difference between the mortality from cancer among Jews and others. He chooses for his data a number of cities of large size which offer the most reliable statistics obtainable for such an inquiry—London, Amsterdam, Vienna, Budapest, Warsaw, Lodze, and Leningrad. The buccal cavity, penis, breast, uterus, ovaries, and gastrointestinal tract are the sites considered.

Contrary to the view once held, it is

found that the total incidence of cancer among Jews follows closely its incidence among other citizens. There is a closer parallel between the Jews and non-Jews of any city than between the Jews of different cities. The author concludes that there is no evidence of a Jewish immunity.

Some organs are more, some less, affected in Jews as compared with non-Jews, and in certain respects these differences are remarkable. The reasons are not clear.

Fatal cases are comparatively rare among Jews in cancer of the buccal cavity, penis, and uterus. The rarity of syphilis among Jews seems to account for the first, circumcision for the second, and certain practices of a hygienic nature required of Jewish women by their religion for the third. Cancer of the breast was found to be neither more nor less prevalent among Jewish women than among others. Ovarian cancer occurred more often in Jewesses, but the number of instances recorded was not large enough to warrant any interpretation. Cancer of the gastrointestinal tract and especially of the intestines was decidedly more frequent among Jews. The author finds it difficult to account for the excess of gastrointestinal cancer among Jews, but offers several possible explanations.

It is interesting to observe that Dr. Sorsby does not seem to consider the possibility that a racial factor may exist and manifest itself in a characteristic organ susceptibility or resistance, and yet this is possible. It is entirely reasonable to suppose that Jewesses inherit an unusual resistance toward cancer of the uterus and an unusual susceptibility to gastrointestinal cancer.

In view of the large amount of labor which he has put upon his excellent research, it is curious to note that the author seems to see only one possibility in the way of a racial peculiarity: apparently he thinks that if Jews are more

or less susceptible to cancer than non-Jews, this fact should make itself apparent in all the organs of the body.

It should be remarked in passing that Dr. Sorsby, like practically every other investigator in his field, assumes that, in cancer, "incidence" and "mortality" are interchangeable terms.

These criticisms by no means detract from the value of the book. Rather, they point to an extension of this particular field of inquiry. No kind of cancer research is so commonly attempted, and, as ordinarily conducted, so incompetently handled, as statistical and epidemiological investigation. A prospect of genuine service lies ahead of really qualified workers in this field.

GEORGE A. SOPER

*Tumbling Illustrated—By L. L. McCloy. Illustrated by D. N. Anderson. New York: Barnes, 1932. 212 pp. Price, \$3.00.*

This profusely illustrated book on tumbling, containing in 212 pages some 666 different exercises, is designed for the use of physical education teachers who may wish to give instructions in tumbling, and also for the use of individuals who wish to find new exercises or to perfect themselves in this phase of physical activity.

Tumbling has for many people a life-long interest, it "is not a temporary fancy, but a life-long interest from early childhood to old age. Evidence of this is seen on the bathing beach, the lawns or in the gymnasiums, where all ages will attempt such stunts as the cartwheel or standing on their heads and hands." These exercises are grouped under certain major headings: individual; couples' exercises; one performer and thrower, etc.; and are graded as to difficulty. The exercises are named and very instructively illustrated by line drawings which are followed by hints as to procedure in an effort to render the exercise easier.

For those teaching or interested in tumbling this would be a very desirable work, and probably is, at present, the most complete of the descriptive texts in this field. CHARLES H. KEENE

**Handbook of Tropical Fevers**—By N. P. Newell, M.D., and W. H. Kauntze, M.D., New York: Wood, 1932. 285 pp. Price, \$6.00.

The authors have given us an unusually interesting book on the subject of tropical fevers, based on an experience which commands respect and attention. In addition to this, they have consulted the best authorities on tropical diseases throughout the world. One naturally feels some hesitation in reviewing such a book, as many of the diseases are practically unknown in the temperate zones or occur so rarely that few people have had any experience with them on which to base opinions.

The authors treat blackwater fever as a special disease, but express their belief that at least 2 and perhaps 3 diseases have been confused under this general name. While stating that the etiology of the disease is uncertain, they lean to the opinion that subtertian (*estivo-autumnal*) malarial infection is the primary factor. Quinine is ruled out on the very just ground that blackwater fever was recognized by Hippocrates; long before quinine came into use. However, they admit that in some cases quinine may produce hemoglobinuria, and give a case which came on after administration of 5 grains of the drug, which resulted fatally.

The most serious criticism of the book is that in spite of the long list of authors quoted, there is a notable absence of Americans. In this country we are inclined to think that Americans, and especially the Army Commission, had much to do with the clearing of the etiology of breakbone fever. In the 18 pages devoted to yellow fever, no mention is made of the name of Carlos

Finlay—which he surely deserves. In this connection, we are glad to note, however, that Noguchi's error in believing that the *Leptospira icteroides* was the cause of the disease is corrected. The name of no American is mentioned in the chapter on bubonic plague, though we are accustomed here to believe that very important work was done, especially in connection with the pneumonic type of the disease, by Teague and others. Altogether, the book is up-to-date, interestingly written, and correct as to facts. The printing and make-up are excellent.

MAZÛCK P. RAVENEL

**Communicable Diseases for Nurses**—By A. G. Bower, M.D., and E. B. Pilant, R.N. (2d ed.) Philadelphia: Saunders, 1932. 358 pp. Price, \$3.00.

This book shows the practicality of having a physician and a nurse collaborate in writing a textbook for nurses. The first part, which deals with definitions of terms in communicable diseases, medical aseptic technic, and care of communicable disease in the home, probably could not be improved upon for clarity and completeness.

The different communicable diseases are then dealt with very effectively and completely under the headings of definition, analogy, mode of infection and conveyance, immunity, symptoms, complications and sequelae, prognosis, treatment, and nursing care.

In the chapter on rabies under diagnosis, however, the authors state that if a dog is obviously rabid it should be immediately killed and the diagnosis confirmed by either finding the Negri bodies in its brain or by inoculating some of this brain substance into other animals. Why take a second animal when the one under observation will serve as a laboratory animal? An animal living through the ordeal will prove himself non-rabid. If a person is bitten

on the face start Pasteur treatment immediately and wait for diagnosis. If it proves negative stop treatment; no harm has been done.

It is disappointing to find Vincent's angina and ringworm so briefly mentioned, each in a paragraph describing another disease. Where do scabies, athletic foot, and pediculosis come in? All these diseases except athletic foot are on the list in "Standard Regulations for the Control of Communicable Diseases," published by the American Public Health Association, and they are serious problems to nurses in the public health nursing field who can never find information enough about them.

The book is excellent. Nurses, mothers and perhaps the physicians need it. Its only sins are those of omission. EVA F. MACDOUGALL

**Mental Healers—Franz Anton Mesmer, Mary Baker Eddy and Sigmund Freud—By Stefan Zweig.** *New York: Viking Press, 1932. 363 pp. Price, \$3.50.*

The author, who says that he is not a mesmerist, a Christian Scientist or a psychoanalyst, and is not moved to write about these subjects through his fanatical belief in the efficacy of any of them, nor through gratitude, has given us an exceedingly interesting study of 3 outstanding characters who he believes while "going their several ways, have worked upon the same principle and brought healing to hundreds of thousands—Mesmer, by means of suggestion,

strengthening the will-to-health; Mary Baker Eddy, by the anesthetic ecstasy of faith, conjuring pain and sickness out of the world; Freud, by rendering the patient aware of the conflict that burdens the unconscious and thus enabling him to escape its spell." He evidently believes strongly in the influence of the mind on the body but in his analyses seems to leave out of consideration the fact that many of the so-called healed people were not sick physically to begin with.

The life histories of the 3 persons selected follow the usual lines and are accurate according to the testimony of authorities. In treating of Mrs. Eddy, he goes more into her love of money and eagerness to collect it than many others do. We confess it rather jars us to have the name of a great man like Freud considered along with the other two, and especially Mrs. Eddy. Mesmer and Freud have taught us much which is worthwhile. Mrs. Eddy has certainly revealed a twist of the human mind which is astonishing and does not tend to strengthen our faith in the average of the intellectual level.

Though we have not seen the original, we judge that the translation is excellent. Certainly the English is good and has been put into a most interesting and readable form. The book can be read by any educated person with pleasure as well as profit. Specialists doubtless can detect flaws not evident to the average reader.

MAZŮCK P. RAVENEL

# A SELECTED PUBLIC HEALTH BIBLIOGRAPHY WITH ANNOTATIONS

**Complicating the Diphtheria Picture**—"The conclusions drawn from a survey of diphtheria in Leeds in recent years, . . . are as follows: (1) There are two forms of diphtheria bacillus. (2) The *B. diphtheria gravis* is associated with severe toxic cases. (3) The *B. diphtheria mitis* is associated with milder cases of the disease. . . . (4) The increased virulence of diphtheria in Leeds is due to an increased prevalence of *B. diphtheria gravis*."

ANDERSON, J. S. The Trend of Diphtheria. Pub. Health, 45, 7: 198 (Apr.), 1932.

**New York State Health Survey**—This summary of the extensive findings and recommendations of the State Health Commission, now published in book form, gives an excellent bird's-eye view of what good state health administration should be.

ANON. State Health Commission Completes Its Work. Health News (New York State Dept. of Health), 9, 14: 53 (Apr. 4), 1932.

**Smallpox Trends**—Statistical evidence in support of the statement that: "The efficacy of smallpox vaccination . . . is shown by the progressive decline . . . in central and eastern Europe where vaccination has become general, while the disease . . . spreads in England and the United States where vaccination is not in fact universally compulsory."

ANON. Trend of Smallpox Incidence in Civilized Countries. Pub. Health Rep., 47, 15: 837 (Apr. 8), 1932.

**Typhoid Fever in 1931**—The total typhoid rate for the large cities (over 100,000 population) is almost the same as for the two preceding years. Twelve of the 93 cities had no deaths, the largest number so far recorded.

ANON. Typhoid in the Large Cities of the

United States in 1931. J. A. M. A., 98, 18: 1550 (Apr. 30), 1932.

**All That's Wrong with Public Health**—The author at his best—and worst. If his indictment of health administration is half true, it is a serious charge indeed. The trouble is, it isn't. The particulars which he advances may be in part the truth, but the general impression left by the story is not. The paper, however, will delight *Mercury* readers, and infuriate a few health workers. The author completes his picture by labelling health officials "communistic radicals" than which nothing could be more completely damning.

CLENDENING, L. Hygeia vs. Aesculapius. Am. Mercury, 26, 101: 28 (May), 1932.

**Health Examinations**—The history of the present ambitious health examination program in New York City holds much of interest to all who are concerned with health promotion.

GALDSTON, I. The Health Examination Idea. Millbank Quart. Bull., 10, 2: 81 (Apr.), 1932.

**Virulence of BCG**—A British research worker inoculated BCG into guinea pigs, monkeys, rabbits and goats, producing lesions which tended to heal, the bacilli within them dying out. His conclusions are: "The results of my investigations support the contention of Calmette that BCG may be used as a vaccine without risk of causing progressive lesions."

GRIFFITH, A. S. A Study of BCG Strain of Tubercle Bacillus. Lancet, 222, 4: 303 (Feb. 6), 1932.

**Undulant Fever**—An excellent summary of the whole subject of undulant fever covering etiology, symptoms, diag-

nosis, treatment and epidemiology for those who have not kept abreast the voluminous literature on this topic.

HASSELLTINE, H. E. Undulant Fever. *Pub. Health Nurs.*, 24, 4: 181 (Apr.), 1932.

**Possibilities of Scurvy**—Although scurvy is seldom seen, due to the general dietary improvement, it is quite possible, if not probable, concludes the author, that economic conditions here and abroad may entail a return of scurvy both in infants and older persons.

HESS, A. F. Recent Advances in Knowledge of Scurvy and the Anti-Scorbutic Vitamin. *J. A. M. A.*, 98, 17: 1428 (Apr. 23), 1932.

**Dried Lactic Acid Milk**—The clinical results of a comparative feeding study indicate "that dried lactic acid milks can be used under the same conditions as cultured sweet milk and cow's milk plus U. S. P. lactic acid."

Family Health

### PENNSYLVANIA PUBLIC HEALTH ASSOCIATION

**T**HE Pennsylvania Public Health Association had its annual meeting on May 26 and 27, in Pittsburgh. Many important papers were presented, including one on "The Advantages of a Municipal Health Center" by Charles B. Crittenden, M.D., Director of the Angeline Elizabeth Kirby Memorial Health Center, Wilkes-Barre; "Health Conservation in Middle Age" by Victor G. Heiser, M.D., of The Rockefeller Foundation, New York; and an address on "Adventures in Health Education" and the "Shanghai Cholera Parade" moving pictures by W. W. Peter, M.D., Director of the Health Bureau of Cleanliness Institute, New York.

### SOUTH CAROLINA PUBLIC HEALTH ASSOCIATION

**T**HE annual meeting of the South Carolina Public Health Association

was held April 19 at Columbia, S. C. The officers elected were: John B. Setzler, M.D., Columbia, S. C., President; Laura Blackburn, R.N., Columbia, S. C., Vice-President; and Lois Orr Preach, R.N., Anderson, S. C., Secretary-Treasurer.

### PENNSYLVANIA SEWAGE WORKS ASSOCIATION

**T**HE Pennsylvania Sewage Works Association will hold its Sixth Annual Conference at State College, Pa., on June 22–24. It will follow the Conference of the Pennsylvania Water Works Operators' Association, to be held on June 20–22. Among the subjects to be discussed are: the new Allentown sewage treatment plant—shown in motion pictures—and that at Erie; "Sludge Digestion Experiences at Baltimore," "Explosion Hazards of Gas from Sewage Sludge Digestion Tanks," and "Insect Control."

### ANTI-MOSQUITO MEETING

**T**HE Tenth Annual Meeting of the Florida Anti-Mosquito Association was held at Clearwater, Fla., March 14 and 15. The U. S. Public Health Service and the A. P. H. A. were represented by Dr. T. H. D. Griffiths, and the U. S. Department of Agriculture had as its representatives Entomologists McNeel and Hull. The Georgia State Board of Health sent its Chief Engineer, L. M. Clarkson.

The program was interesting and varied, covering the problems of mosquito, malaria and sand-fly control. Progress reports were presented by the three Mosquito Control Districts of Florida and by the Taylor County Health Unit of the state.

The meeting was attended by repre-

sentatives of the Florida State Board of Health and others interested.

#### CHILD LABOR CONFERENCE

THE National Child Labor Committee held its 27th Annual Conference in Philadelphia, Pa., on May 17. The general subject was Child Labor and the Schools in a Depression Period.

#### FREE HOSPITAL SERVICE

AT the annual distribution luncheon of the United Hospital Fund, in New York on May 9, a total of \$575,000 was presented to the presidents of the 55 associated hospitals, representing the share of each in the proceeds of the public collection for the provision of free hospital service, apportioned among them on the basis of free service rendered during the preceding year. The reports for 1931 show that the 55 hospitals gave a total of 1,752,998 days of free care in their wards; of this total, 1,043,000 days were credited to the 29 general hospitals and 709,998 to the 26 special hospitals. The free visits to the Out-Patient Departments of these hospitals increased 17 per cent over those of 1930.

#### TWINS

IN every 50 live births in Maryland, in 1931, there was an average of one set of twins. The total number of live births recorded was 28,705. This number includes 298 sets of twins—596 children—or 2 per cent of the total. The ratio was the same for Baltimore City, and the counties, for both white and colored races. The report of the U. S. Bureau of the Census, for births for 1928, the latest period for which complete records are available, gives a total of 2,233,149 births in the U. S. Birth Registration Area, comprising 94.4 per cent of the total population. There were 23,863 sets of twins—47,726 children, or 2 per cent of the total. These figures, like those for Maryland,

do not include the plural births in which one or both children died. These figures indicate that one set of living twins was born to each one hundred mothers.

#### EYE COURSES

THE National Society for the Prevention of Blindness plans to sponsor, next fall, two courses for medical social service workers in eye hospitals and clinics. The society will coöperate with Washington University, St. Louis, and the Massachusetts Eye and Ear Infirmary, Boston, in giving these courses which will probably extend through a period of 16 weeks. A few scholarships may be available later. Those interested should communicate with Eleanor P. Brown, Secretary of the National Society for the Prevention of Blindness, 450 Seventh Avenue, New York, N. Y.

#### PERSONALS

C. HAMPSON JONES, M.D., Health Commissioner of the City of Baltimore, died April 11 in his 74th year. Dr. Jones was associated with the Baltimore Health Department since 1896, with the exception of the years 1915 to 1919. He has served as Commissioner of Health for 14 years. He was a member of the A. P. H. A. since 1915 and was made a Charter Fellow in 1922. He served the Health Officers Section as Vice-Chairman, 1926–1927, and as Chairman, 1927–1928, and was a member of the Governing Council of the Association, 1923–1924.

HARRY E. RANSOM, M.D., was appointed City Health Commissioner of Des Moines, Ia., to succeed Harley L. Sayler, M.D. Doctor Ransom is very well qualified to serve as chief of the health department by virtue of many years of service as an assistant to former commissioners.

## CONFERENCES

## Interpretation of Laboratory Findings in Rural Spring Water Supplies\*

EDMUND K. KLINE, DR.P.H., F.A.P.H.A. AND NELSON M. FULLER

*Director of Laboratories; and Sanitary Engineer; Cattaraugus County  
Department of Health, Olean, N. Y.*

ATTEMPTS to reconcile the results of sanitary surveys and of laboratory examinations in rural water supplies of Cattaraugus County indicated that in supplies from springs, certain periods of the year when laboratory findings became distinctly unfavorable were coincident with the appearance of small numbers of salamanders in the springs. Testing out the assumption that these were related phenomena it seemed desirable to make a study of the salamanders found and to ascertain experimentally whether it was reasonable to suppose that their presence could influence the quality of a water as measured by laboratory tests. This paper is a report of certain phases of such work and is presented in the hope that it will stimulate interest in the problem, and suggest to other workers the possibility of advances in water control technic through the elimination of salamanders from rural spring water supplies.

Salamanders are small amphibians popularly known as salamanders, chameleons, lizards, ground puppies, newts, efts, mud puppies, or hellbenders. Eleven species have been found in Cattaraugus County during our investigations,<sup>1</sup> and 2 additional<sup>2</sup> are reported by Bishop.<sup>3</sup> Of these only 2 have been found in large numbers in springs, *Gyrinophilus porphyriticus*—the purple salamander, and *Desmognathus fuscus fuscus*—the dusky salamander, although 3 other species, *Desmognathus fuscus ochrophaeus*—the mountain salamander, *Eurycea longicaudata*, and *Eurycea bislineata* are occasionally

\* Read before the Laboratory Section of the American Public Health Association at the Sixtieth Annual Meeting at Montreal, Canada, September 14, 1931.

found in springs. The other species are in the main terrestrial or deep water dwellers.

All 5 species are produced from eggs fertilized in the female cloacae by spermatophores either transferred directly from the male or deposited by the male and later drawn into the cloacae. The eggs, usually about 20, hatch about 8 weeks after being laid, producing larval forms provided with external gills and therefore necessarily aquatic. After 9 months to over 2 years, varying with the species,

FIGURE I

*Reprinted from The Salamanders of the Family Plethodontidae, by Emmett Reid Dunn*

the larvae attain a length of 2 inches in *Desmognathus*, and about 4 inches in *Gyrinophilus*, and at that time lose their external gills, thereafter getting their oxygen through the skin and the walls of pharynx and throat. No *Plethodontidae* ever develop lungs. The purple salamander attains a maximum length of about 8 inches, while the dusky and the closely related mountain salamander are only about half as large. The two species of *Eurycea* reach a maximum length of about 5 inches.

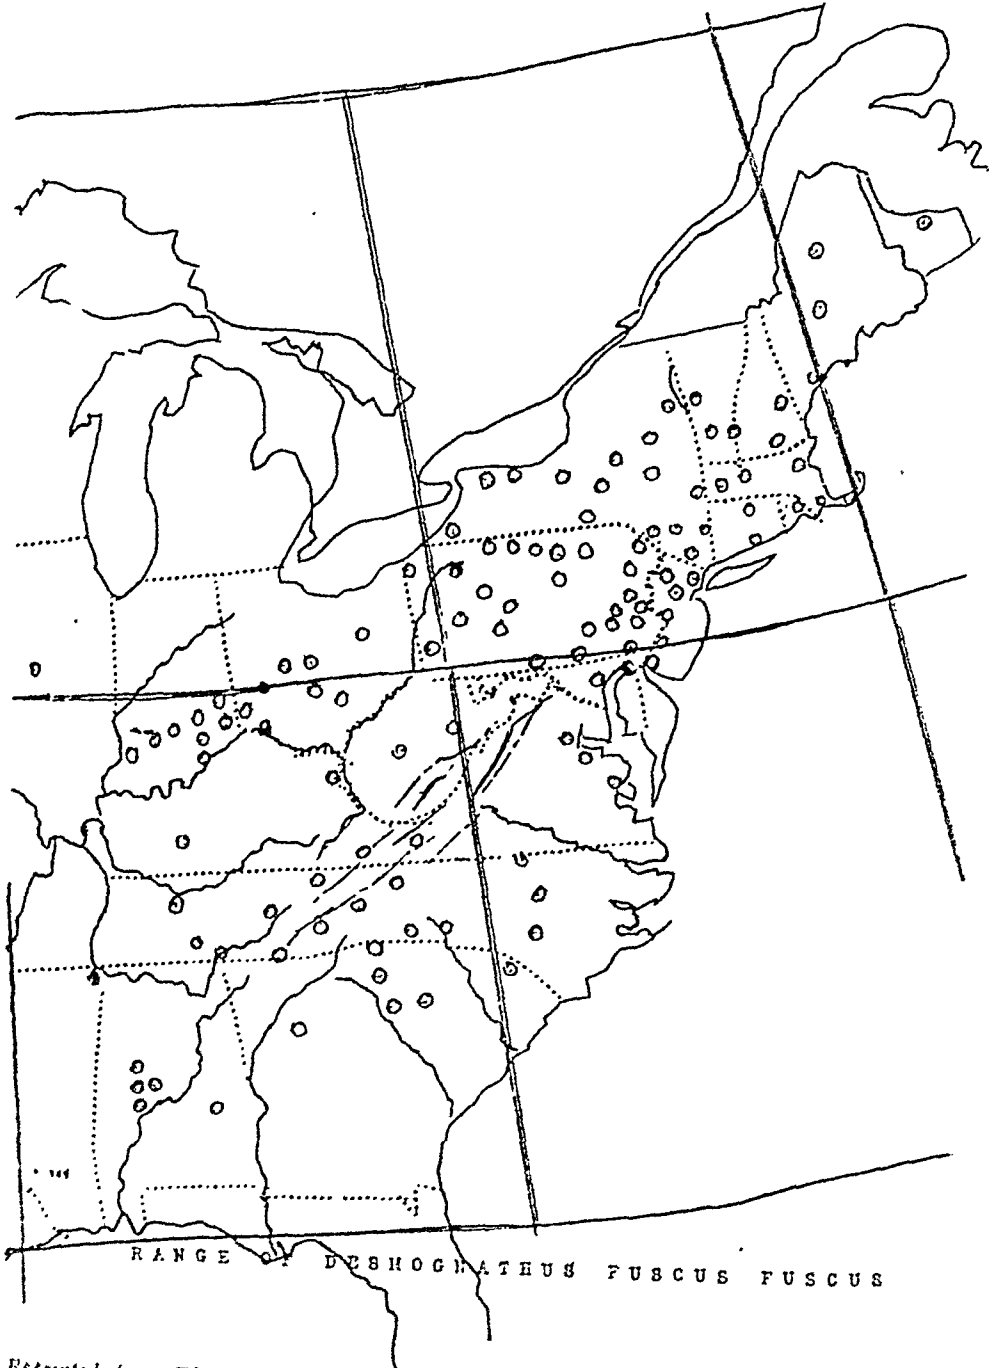

These types of salamanders are confined almost entirely to the Appalachian range, the *Desmognathus* extending somewhat further south, and the *Gyrinophilus* somewhat further north than the central part of the range. Their geographical distribution is well shown on the two charts copied from Dunn's book *The Plethodontidae*.<sup>4</sup> (See Figures I and II.)

We obtained the services of a member of the staff of the American Museum of Natural History<sup>5</sup> to study the distribution and habits of salamanders in the field. Making his first observations in February before the snow had melted from the hills he was able to find salamanders in more than two-thirds of the springs visited, including many which had been located and completely protected according to the recommendations of our State Department of Health. Most of them were remote from inhabited areas, provided with concrete spring houses, protected from surface drainage and surrounded by man-proof fences. Several of these which contained no salamanders on the first or second visit yielded them subsequently. Making his next round in May and June after the snow had melted and the ground was open, he was frequently unable to find salamanders in springs which had shown them formerly, though he soon came to the conclusion that repeated visits at favorable times would again disclose their presence.

The number of salamanders found by careful and continued intensive work on single springs is very surprising. We have taken more than 200 from a spring which frequently failed to yield even one on single visits. According to our evidence, most of the salamanders in any spring at a given time are buried deep within the layers of shale and the number out where they can be seen is very small in comparison with the total number present. In digging out springs we have captured salamanders 10 or 12 feet beyond the point at which the water came to the surface, and as deep as 6 or 8 feet.

In contrast to the usual distribution described, from the middle of May to the middle of June, and again from the middle of October to the middle of November, we found comparatively large numbers,

FIGURE II

Reprinted from *The Salamanders of the Family Plethodontidae*, by Emmett Reid Dunn

chiefly *Gyrinophilus*, on the surface of the ground during the night from 10 P.M. to 3 A.M.—although none could be discovered in the daytime.

During these periods the animals would wander to distances of over 65 feet from the spring in which they were living, and autopsies revealed that they were feeding during such wanderings. They were found wandering in the neighborhood of springs considered to be adequately protected from outside pollution, as well as near those

unprotected. Careful correlation of the number found wandering on land on certain nights with the temperature and relative humidity, failed to show any relationship. Usually one would find several salamanders at a single spring or else none (Figure IV). During the late spring and summer very few were seen on land.

For study of the movements of individual salamanders we passed a small copper wire through the tail just posterior to the anus and tied a numbered tag to this. By this means we have established the fact that individual salamanders wander freely up and down a stream (Figure V). By placing a large number of tagged salamanders in a spring, and after a period of several weeks digging out the head of the spring, we got some idea of how many of the salamander population we were recovering. Of 163 salamanders captured, tagged, and replaced in an experimental spring we recovered only 25, but captured 18 untagged salamanders which had uninjured tails and therefore were never tagged. A study of the possibilities of the distribution of the remaining tagged salamanders leads us to believe that they were buried in the shale along the main water current at a greater distance than we were able to dig out. Observations of salamanders removed from springs and placed at a distance proved that they possessed a sense of direction which enabled them to return regardless of the contours of the land over which they had to travel.

Bacteriological studies of the gastrointestinal tracts of salamanders show that many of them captured in both protected and

FIGURE III

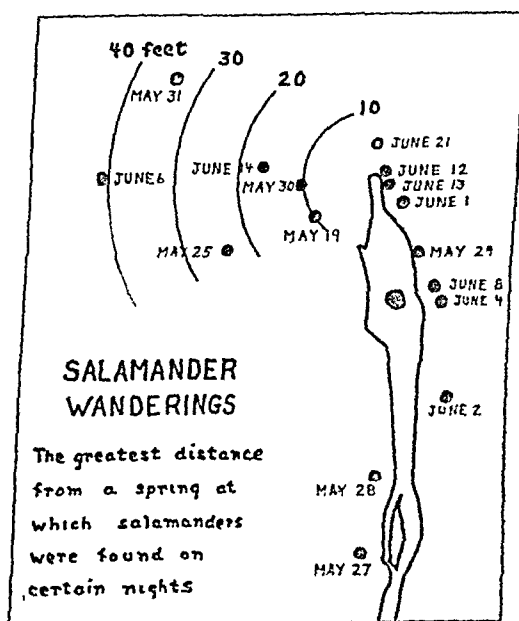

FIGURE IV

unprotected waters contain organisms of the colon aerogenes group. The season and kind of food available seem to influence this, as of 100 salamanders autopsied in February only 11 per cent showed *B. coli* against 66 per cent from a similar series taken from the same springs in May and June.

When placed in sterile water they expel colon bacilli. Our experiments indicate that starving salamanders contain no colon organisms, for we have repeatedly placed those throwing off *B. coli* in flasks of sterile water and, after making daily transfers to similar flasks for a few weeks, have been unable to find colon bacilli on autopsy.

On the other hand, we have very definite evidence that the salamander containing colon bacilli in its intestinal tracts continues to throw them off as long as the intestines contain material suitable for the growth of the organisms, acting as a reservoir or incubator. We fed a salamander *B. coli*, placed him in a tank of running water, gave sterilized food at intervals, and made daily tests of the water at the outlet, for 1 year. We recovered *B. coli* for 253 days. The output was irregular; some days every 0.1 c.c. portion was positive, occasionally, even early in the experiment, all cultures were negative. For the entire year 33 per cent of the 10 c.c. portions tested were positive, as shown in Table I.

There appeared to be no relation between the time of individual feedings and the number of colon bacilli thrown off. During the same period the city water used in the experiment showed only 0.5 per cent of the 10 c.c. tubes positive.

Additional evidence is shown by experiments wherein we fed *B. coli* to salamanders and then transferred them from flask to flask of sterile water, with occasional feedings of sterile food. One animal lived 122 days, and we obtained completely confirmed *B. coli* tests from the final flask; another gave off large numbers over a period of 71 days, when it was drowned. Some idea of the number of colon bacilli thrown off was obtained by plate counts on Endo's medium. The salamander that lived 122 days gave off an average of 36,000 *B. coli* per day, sufficient to contaminate 237 gallons of water so

FIGURE V.—Wanderings of tagged salamander No. 29 (same scale as Figure IV)

Total	1,560	514	33	624	96	15	624	63	10

heavily that 40 per cent of the 10 c.c. portions will show *B. coli*. When we consider that we have found over 200 salamanders in one spring it becomes apparent that pollution from them can be quite significant.

In a series of experiments we either fed *B. coli* to salamanders or else permitted them to remain for short periods in a dilute culture of the organism, carried them in flasks of sterile water for several days, then autopsied them. Cultures of the skin, the mouth parts, the stomach and the peritoneal cavity were uniformly negative, while those of the upper and lower intestines showed *B. coli*.

About half of our cultures meet all the criterions suggested to us as identifying colon bacilli from fecal sources. These have included: methyl red, Voges-Proskaur, indol production, Eijkmann tests, Koser's citrate and uric acid tests, inosite and cellobiose fermentation.

What has been said of the ability of salamanders to continue to throw off *B. coli* after becoming infected also applies to the common newt, *Triturus viridescens*, found in large numbers in some open reservoirs. However, newts do not often wander on land after they once enter the water, although the middle portion of their life is passed entirely on land as the small animal known as the red eft. During this stage they can undoubtedly pick up *B. coli*.

Successful methods to eliminate salamanders from water supplies have not been found. No system of screens keeps them out, and walls sunk in the ground only force them to work their way through

the shale mantle rock beneath or to go around on the surface. A concrete wall sunk to bed rock would certainly stop them but this is not feasible, and all methods fail to eliminate those already present in the deep parts of the shale up the underground stream which feeds the spring. We know a spring which is really a dug well where the ground water has been intercepted at a depth of several feet and the bottom of which is covered with a thick layer of sand. This has never shown salamanders and all samples of water tested over a period of several years have been uniformly good.

Since the elimination of a suitable food supply will undoubtedly serve to decrease the salamander population we are preparing a spring by stripping the ground for a large area around the head and covering the surface with slag, believing that by keeping out earthworms we will decrease the chance of salamanders finding suitable food. We have established the fact that the salamander is unable to exist in water which shows a residual chlorine of 0.2 p.p.m., but have been unable to devise a method of applying chlorine at a point far enough above the spring to affect those residing in the depths of the shale, particularly since most of our springs are fed from several underground streams coming from different directions.

From an engineering standpoint we believe that in the Appalachian area it is desirable to revise our methods of protecting springs. In order to control salamanders it is necessary to build fences proof against both men and animals which will protect an area the boundaries of which will be at all points at least 100 feet from the spring or any outcropping of moisture above the spring. This area should be not only protected against surface drainage but so treated that it will be unsuitable for earthworm and insect life. Since the salamander requires a moist skin to maintain life, the protected area should be stripped so that the surface will be exposed to direct sunlight, and drained so that it will be as dry as possible at all times. Any overflow should be piped beyond the enclosure.

In conclusion may we outline our conception of the rôle that salamanders play in Appalachian spring water supplies. The salamanders live in large numbers buried deep within the shale along the underground streams. At certain seasons they come out from the deep recesses to the surface and travel distances of at least 65 feet overland. Here they feed on insects, worms, fly larvae, or similar living food. Should these be infected with *B. coli* through improper protection of the area from direct fecal pollution or surface drainage the salamanders become infected. Then they return to the depths

and throw off *B. coli* for a considerable time. Laboratory tests on such a water supply would suggest condemnation even though the supply was otherwise unpolluted.

## Transmission of Endemic Typhus Fever

SEVERAL months ago the announcement was made by the U. S. Public Health Service that endemic typhus fever, which has been recognized for several years in the United States, had been shown to be transmitted by fleas.

Additional studies indicate that the rat flea is the agent that transmits this condition. This work has been proved by laboratory experiments and by field studies, all of which have been conducted by the Service. There seems to be ample evidence that endemic typhus fever is spread from rat to rat by the rat flea, and from rat to man by the same agency.

# Getting Public Health Needs Across to Appropriating Bodies by a Municipal Health Department\*\*

HENRY F. VAUGHAN, D.P.H., F.A.P.H.A.

*Commissioner of Health, Detroit, Mich.*

IT is the writer's opinion that the first step in securing a sufficient appropriation for the maintenance of a public health service in a municipal health department is to formulate a program for the establishment of a whole-time health service. To be effective, such service must be manned with a qualified and trained personnel, and blessed with funds sufficient to carry on the essential work. Where funds are lacking, the program itself becomes the necessary fundamental but cannot be executed without the help of public opinion which must be aroused through a combination of the recognized means of health education. Public confidence and support demands a reasonable appropriation for public health service. It is obvious, however, that some individual or group of citizens must take the initiative in bringing the local needs to public attention. Appropriating bodies continuously feel the pulse of public opinion and are guided thereby. Newspapers, clubs, and civic organizations can be extremely helpful.

Not many years ago in one large city, the editor of the principal newspaper decided, after consultation with the health officer, that public opinion had not been aroused to the seriousness of the local tuberculosis problem. An intensive educational campaign was instituted with a 2-column bold type editorial on the first page of the home edition for 60 consecutive days. The stories were prepared by a clever newspaper man who had spent hours in the health department studying the situation and becoming familiar with the community needs for public health nurses and hospital facilities. When the appropriating body met a few weeks later, the politicians fell all over themselves in their endeavor to be first to champion the requested appropriation for clinic maintenance, the employment of public health nurses, and the construction of a sanatorium. These men had

\* Read before the Public Health Nursing Section of the American Public Health Association at the Sixtieth Annual Meeting at Montreal, Canada, September 15, 1931.

sensed popular opinion and were convinced that it was to their advantage to support these particular items.

The history of modern public health procedure in numerous cities throughout the country is replete with instances of this character, where citizens, committees, individuals, and groups, with newspaper support, have molded sentiment in favor of preventive medicine.

If we carefully analyze the Appraisal Forms approved by this Association, we will find no individual section of this measuring stick which deals with public health nursing. There are chapters on vital statistics, communicable disease control, venereal disease, and tuberculosis activities, the health of the child from prenatal to school service, sanitation, milk and food control, health education, and the laboratory service, but no division for nursing. However, a careful survey of the individual items which constitute the maximum rating of 1,000 points which any local health organization can obtain, will disclose the fact that, if we pick out those items toward which the principal contribution is from the public health nurse, the latter is actually responsible for approximately 45 per cent of the maximum rating, 450 of the total of 1,000 points. These include the evaluation of field nursing service, clinic service, health education, and the like. We may fairly conclude that in the modern health organization public health nursing service is responsible for nearly one-half of the entire program, and the health department is justified in expending nearly one-half of its budget for preventive service in its nursing division. Therefore, if we are to sell locally a modern health service, we must give particular heed to the establishment of a well organized, well qualified, efficient nursing staff. It naturally follows that in selling the health program, we must, of necessity, sell the nursing service.

The public health nurse is in a unique position in that her duties are such that her work is appreciated by the public more readily than that of others in the health organization. She becomes the family counsellor, she enters the home with a spirit of willing suggestion and hearty coöperation, she comes as a counsellor and as an adviser, and she endears herself to the hearts of the mothers and young children of the household. On the other hand, the physician or the inspector more frequently appears as the agent of the law, who inflicts quarantine or serves notices for the improvement of environmental sanitation. It is much easier to establish a program for the conservation of child life and the reduction of maternal mortality than it is to revolutionize milk and food sanitation by requiring pasteurization, or promulgate a housing code to wipe out slums and abate nuisances.

Each new friend cultivated and won over to the principles of infant hygiene and vigorous health for the school child becomes a propagandist in bringing popular opinion to the support of the health service.

A campaign for the reduction of infant mortality provides the health officer with his sales talk. A map of the city is prepared, showing the births and deaths under 1 year in each of the numerous sanitary districts into which the city has been divided. From these, we readily calculate the infant mortality. There will be districts in which the rate among infants is below the average; there will be others in which there are no deaths. On the other hand, there will be areas in which the death rate is far in excess of the average for the city. It is in such districts that a health department should intensify its educational program, establish its clinics, and release its public health nurses as home visitors. The results will be immediate. The mortality rate will decrease until it approximates or even falls below the average.

A map showing the loss in child life before and after the establishment of such a campaign becomes a potent tool in the hands of the health officer before his appropriating body. It is possible to show that with a given appropriation for nurses and clinic service a certain definite number of infant lives can be saved each year in the specified areas. These areas can be referred to specifically by giving the names of the streets forming the boundary. With the assurance of the health officer that for a given appropriation, he can save a specified number of lives, it takes a rather hardened body of politicians to refuse a reasonable appropriation. In other words, it can be shown that for a given expenditure a certain quantity of health can be purchased. Grant the health department the means with which to employ public health nurses, and infant lives can be conserved.

The public health nurse's prime function is to teach health. She plays an important rôle in every function of the health department which depends for success upon health education. On every occasion the health officer should endeavor to impress upon the public mind this important function of the nurse.

During the past 3 years, the Detroit Department of Health has been putting into operation a program of participation by the general medical practitioner in official public health procedure, the ultimate objective of which is to secure the sympathetic and wholehearted support of the medical profession in order that the general practitioner will not only practise curative medicine, but will actively take his part and share of the responsibility in the preventive medical program.

A beginning was made in the field of diphtheria prevention. All free clinics were abandoned and there were established a group of 1,100 coöperating physicians who have performed the service of immunization in their own offices. There has been a series of post-graduate conferences in communicable diseases which has assisted in standardizing the service and stimulating medical interest and coöperation. For service to indigents, physicians have been paid by the Department of Health at a modest rate.

To bring about the protection of a large number of children involves a 3-cornered coöperation between the public, the medical profession, and the department of health. The department, through its division of health education and through its nursing service, must instruct parents. The department must also prepare the medical profession for the service which it is to perform. Once the parent has learned what service is expected and the value of such service, and how much it will cost, you can be assured of at least the coöperation of the intelligent members of the community.

During the first few months of the Detroit campaign to stimulate public interest, the educational propaganda necessary to give impetus to the work included newspaper stories, paid advertisements, posters, lectures, bill-board advertising, radio talks, and the generous distribution of literature. The results were not noteworthy, as it was found that we reached approximately 18 to 20 per cent of the children who we estimated were in need of service. The plan was then conceived of expanding the educational program by having a house-to-house canvass made by public health nurses. The objective was to secure the protection, through immunization in the physicians' offices, of all children between the ages of 6 months and 10 years. For 4 months 112 of these health educators devoted their whole time to this work and canvassed a total of 163,402 families. At the time of the first nursing visit, it was found that 15 per cent of babies between 6 months and 1 year of age had already received protective treatment; 43 per cent of the preschool group; and 59 per cent of the school group were protected. As a result of this intensive sales-drive by the public health nurse, the per cent of protected children was increased to 52; that of the preschool child to 70; while that of immunized school children increased to 80. What better demonstration could we have of the results which the public health nurse can obtain by winning parental confidence and coöperation to such extent that 73 per cent of the children below the age of 10 years is actually protected against diphtheria?

Now you may inquire as to what bearing this campaign has upon

the problem of securing an appropriation for a nursing service. It has a very important influence. Public attention had been focused upon the needlessly high diphtheria death rate, and the city council had expressed its willingness to back any reasonable program and expenditure as long as results could be obtained. The diphtheria death rate has been cut to one-fourth and the health officer charges the responsibility for this reduction largely to the nursing service of the department of health. It becomes an extremely potent argument for appropriations.

Briefly, let it be said that the public health nurse is the largest single factor in the modern municipal health organization. In popularizing the work of the department, the health officer must inevitably bring forward the tremendous influence which the well trained nurse is manifesting in the reduction of the death rate and in the elimination of needless sickness and distress. May we again repeat that a plan for a well rounded, whole-time local health service is the first essential, and upon this foundation must be created a public confidence in the work of the public health nurse.

## German Society of Pediatricians

THE Society of Pediatricians of Germany has recently issued a statement expressing its apprehension over the health of the children of Germany and Austria. The statement points out the general deterioration of the children's health; their low resistance to disease, the increase in the cases of tuberculosis, and other conditions similar to those prevalent in a time of famine. It warns the authorities against the dangerous consequence of further reduction of the expenditures for the care of sick children and for child welfare in general, and concludes by saying that "if economy must be effected it should not be at the expense of the children who are the future of the country."—*Gesundheitsfürsorge für das Kindesalter*, Berlin, 6, 6:457, 1931.

# Training in Administrative Procedures of Personnel for Child Health Work\*

JOHN A. FERRELL, M.D., DR.P.H., F.A.P.H.A.

*Associate Director, International Health Division,  
Rockefeller Foundation, New York, N. Y.*

PRESUMABLY, the principles of administration that should be taught to those who are to engage in child health work do not differ materially from those that should be taught to personnel that is to serve in other branches of the health department. Administrative procedures appropriate for the health department as a whole, and covering the work of its several branches, should be suitable for the bureau of child health work. Certainly the local health organizations of counties and towns cannot, as a rule, have special personnel for particular problems. The small staffs of these organizations have to spread themselves over the entire field of public health, including child health work; there is no possibility of special administrative procedures for special branches of the local health service. The personnel requires training that is broad and general; there is little chance for specialization.

Irrespective of whether the teaching in administrative practices is to be for specialists in child health work or some other branch of the health service, or for general workers in the field, certain questions will arise:

1. What persons or groups are to be taught?
2. What are to be their duties and what should they be taught?
3. How should public health training, the factor of greatest fundamental importance for progress in child health work, be made available for health personnel?
4. What is the outlook for the future?

The personnel to be taught includes present and prospective employees of national, state, and local health agencies, both private and governmental, principally the latter. There will be the technical and administrative staffs of the central organizations of the national, state, and city health services, and the general field workers of these agencies, and those of counties and towns, including health officers,

\* Read before the Child Hygiene Section of the American Public Health Association at the Sixtieth Annual Meeting at Montreal, Canada, September 17, 1931.

nurses, and inspectors. Although the technical experts of the central organizations will always be relatively few, the field workers will be numbered by the thousands when local health services have been developed throughout the nation. Even now their number is exceedingly large. The following ratios of health personnel to population have been suggested by one writer: a medical health officer for every 20,000 inhabitants, a sanitary inspector for every 10,000 inhabitants, and a public health nurse for every 5,000 inhabitants. However, these ratios have been reached in only a few places.

The facilities necessary for effective child health work include practically all those supplied by the average health departments of states and cities. There must be provision for the collection and analysis of birth, morbidity, and mortality statistics; diagnostic and biological laboratory service; divisions for preventable and contagious diseases, for sanitary engineering, for local health services, including nursing; and services for dealing with special diseases and special problems. All of these branches, administratively and scientifically, are able to play essential parts in protecting the health of children.

Each division or bureau of a health service has a director or chief, who is expected to be a specialist or technical expert in his particular field. For example, the director of a bureau of child health work should be a first class pediatrician; through university courses he should have acquired special knowledge of public health, including public health administration; and he should be experienced in health organization work. Such a background of training should enable the director to maintain a harmonious relationship with the central health organization and its other bureaus, and with the local health organizations upon which he must depend for carrying out the measures in which he is particularly interested. He should be qualified to assist the chief executive in selecting competent personnel, and to give that personnel special training in his field. If he has assistants they should likewise have special technical and general public health knowledge to enable them to share in his many duties and responsibilities.

The staff members of local health organizations are general field workers; they correspond to general practitioners in medicine. They should all have a general knowledge of public health work, and each should have some special knowledge in order to carry out his or her share of the organization's program; but they are not expected to be technical experts in pediatrics, bacteriology, statistics, tuberculosis, or other specialties. These men and women should know the health laws, the rules and regulations of the health organization and its administrative principles. They should know how to plan and carry

out a program of work; how to reach and deal with problems in the home, the school, the clinic; how to accomplish results both by their own labors and by inspiring others to work. They should be teachers—translators of scientific knowledge into simple terms which the laity will understand. In short, they should be emissaries of health to all the forces of the community.

The impression that has prevailed in the past that any physician or any bedside nurse is qualified for public health work is now recognized to be wrong in responsible circles. The public health worker must have special training, since public health is a specialty for which specific knowledge and training are necessary. It would not be practicable to present here a detailed statement of all that should be taught to the prospective health worker. In general it may be said that the courses required for certificates or diplomas by the best equipped schools of public health would cover the essential special knowledge, including general administrative procedures. The directors of health bureaus and their associates should have had such courses, as should also the local health officers in so far as this is possible. The nurses should strive to take the courses required for university diplomas in public health nursing. University courses for sanitary inspectors have not been established or utilized to any great extent, consequently inspectors are very largely dependent for training upon the school of experience and training stations. University courses, then, should be taken by all health workers, and this instruction should be supplemented by field experience.
